Quite apart, however, from this consideration, what are the actual results of anti-rabic inoculation? Certainly the efficacy of Pasteur's method is not to be judged by the figures published by his school. M. Grancher is roundly accused of juggling with numbers to such an extent as to make his claims appear utterly unreliable. The great mistake the Pasteurites make, is to consider all bitten subjects, who present themselves for treatment at the Institute, as infected with hydrophobia.

Now M. Lutaud claims to have kept an accurate record of the deaths due to rabies, both before and since the Pasteur system came into vogue. These would show that rather more persons succumb to the disease now than formerly. And it is highly probable that some die in consequence of the treatment they are subjected to, who would have survived if left unmolested. Altogether the Pasteur system makes a very poor showing, when thus exposed at the hands of a hostile critic.

But, as already intimated, every controversy has two sides. Those who uphold the Pasteur doctrine quote figures, which, if reliable, put the matter in a decidedly favorable light for the advocates of anti-rabic inoculation. The *Times* gave a summary recently, of what M. Grancher had said relative to the progress of this system.

It may be remembered that human beings were first inoculated with Pasteur's attenuated virus in 1885. Up to July 1, 1888, 5,384 persons had been treated in Paris. In 1886 the number inoculated was 2,682, in 1887 it was 1,778, and in the first six months of the present year it was 914. The rate of mortality in the first year was 1.34 per cent. It fell to 1.12 in the second year, and in the first half of the present year it was only .77. The mortality that furnished these rates included the deaths of persons in whom the poison had become developed when they were subjected to treatment. It has been estimated that before Pasteur's method was used the mortality was about 16 per cent. of the persons bitten.

There have been established seventeen branch laboratories. Seven of these are in Russia, five are in Italy, and each of five other countries—Roumania, Austria, Brazil, Cuba, and the Argentine Republic—has one. Nearly 4,000 cases have been treated in these branch institutions. At St. Petersburg 484 have been inoculated, with a mortality of 2.68 per cent. The number of those treated at Odessa has been 1,135, the rate of mortality under the mild treatment in 1886 having been 3.39, while in the two following years, under the "intensive" treatment, it fell to .58 and .65 respectively. In Havana 170 were inoculated, with a mortality-rate of .6 per cent. The high rate of mortality in Russia is accounted for by the fact that many of the patients had been bitten by mad wolves.

This then is the other side. For our own part we shall wait for further developments, believing that it is impossible at present to say positively either that Pasteurism for hydrophobia is a glaring fraud and gross imposition, or that it is one of the greatest boons yet conferred by medicine upon suffering humanity. There is a final thought that suggests itself to us. We have now a "Palace of Hydrophobia," although rabies claims but few victims every year. Will not some generous charity soon give us palaces of diphtheria, of scarlatina, of typhoid, and other possibly preventable diseases, that still swell our mortality lists to unnatural dimensions.

ASTHENIA AND NEURASTHENIA.

A correspondent of the *Boston Medical and Surgical Journal*, Dr. Philip C. Knapp, has furnished to that journal voluminous etymological evidence to the effect that the accent in neurasthenia should be upon the penult. A

professor at Harvard has even been called in to help fix the accent on the i. We commend the learned gentlemen for their scholastic efforts in behalf of the penult. The dictionary authority for neurasthenía is sound; we have not denied it. But common usage is greater than etymology, and is the final arbiter.

The later lexicographers, like Stormonth and Thomas, recognize this, and put the accent in anasthenia and sthenia on the antepenult. The eminent Harvard professor and his esteemed coadjutor do not seem to be aware of this fundamental principle of orthöepy. Such is the penalty of growing up with wax in the ears; perhaps, following their own rules, they still say Alexandría, and vertígo. The eminent professor who cannot understand how asthenia can come from σθενος would do well to consult Stormonth and Thomas, who give such an etymology, and whose modest lexicographical works contrast not unfavorably with Professor Goodwin's textbook for school-boys wishing to learn the rudiments of Greek.

We trust that our Boston friends will get over their Passion for the Penult, with maturer years and larger aural experiences. The tendency of modern usage is to throw the accent back, and such words as asthenia and neurasthenia will not have their accepted pronunciation changed by the sciolistic efforts of closet philosophy. Neurasthenía is the language of the provinces.

"What did the doctor pronounce your ailment?" inquired she, with a tremor of anxiety in her tone, as she came into her husband's sick-room.

"He pronounced it as if it were spelled bronkeetus," exclaimed the indignant Bostonian, straightening himself up in bed, "and I requested him at once to make out his bill and go."

THE SIGNIFICANCE OF PEPTONURIA DURING PREGNANCY.

The presence of peptone in the urine of pregnant women may be taken, according to Dr. Koettnitz, to indicate the death of the fœtus. This conclusion he bases on the observation of three cases in which the occurrence of peptonuria was followed by the expulsion of dead products of conception (*Allgemeine Medicinisch Central-Zeitung*).

It is well known that peptone appears in the urine in conditions accompanied by the disintegration and absorption of albuminoid bodies, notably the leucocytes. Similar conditions are present in the case of the death of the fœtus in utero. It is to be remembered that the liquor amnii is itself an albuminous fluid, and the fœtus is, of course, largely composed of albuminoid bodies. The amniotic fluid tends to macerate and decompose the dead fœtus, the placenta also dies off, and hence we have the absorption of bodies that lead at once to the appearance of peptone in the urine.

In the normal puerperal state peptonuria is never observed. The author also failed to discover this symptom in the case of a pregnant woman afflicted with chronic nephritis.

It is to be hoped that others will be able to confirm the significance of peptonuria in pregnancy, for this would then give us a valuable diagnostic sign that is at present often wanting, especially where the death of the fœtus takes place in the earlier stages of pregnancy.

News of the Week.

Dr. A. L. Loomis explains his Relations with the Late Dr. M. N. Miller.—Dr. Alfred L. Loomis was examined on Monday in accordance with the order obtained from Judge Freedman of the Superior Court, to enable Mrs. Margaret Alden Miller to make out her complaint in the suit against him, as administratrix of her husband, Dr. Maurice N. Miller. Mr. Francis L. Stetson, of the firm of Bangs, Stetson, Tracy & MacVeagh, appeared as counsel for Dr. Loomis. Mrs. Miller charges that her husband, who was employed at the Loomis Laboratory, did a great deal of work for Dr. Loomis in 1888, and especially that he prepared the greater part of a paper on "The Cardiac Changes in Bright's Disease," read by Dr. Loomis before the Association of American Physicians at Washington, in September, 1888. Dr. Loomis testified that Dr. Miller's work on the essay consisted in engrossing some tables and copying them afterward for publication. He did not revise it or do any original work on it. For the engrossing he was paid $25, and for copying for publication $10, although he said he didn't know as the copying was worth anything. Mrs. Miller's counsel had in court Dr. Loomis's original tables from which the engrossed copy was made, and the manuscript of the essay was put in evidence. It was all in the handwriting of Dr. Loomis or his wife. Dr. Loomis said Dr. Miller was paid $70 per month for his work at the Loomis Laboratory during ten months of the year. He collected the dues from the students, and accounts were settled about the first of every month. The settlement for November last was never made. Dr. Miller said early in December that he had a check for $680, and $180 in cash which he had collected for dues. Dr. Loomis took the check, but found he had no blank check to fill out for Dr. Miller's salary, and so told him to keep the $180 until the next day, when they would square accounts. He never saw Dr. Miller again, and when he presented the check for $680 at the bank for payment, he was told there was no cash to Dr. Miller's credit. It was apparent from Dr. Loomis's testimony that his relations with Dr. Miller had always been pleasant, but it was not pleasing to Mrs. Miller's counsel, as it showed that Dr. Loomis had written his own essay and prepared the tables for Dr. Miller to engross.

The New York Pathological Society, which has been wandering about a good deal, has now been obligingly provided with quarters at the College of Physicians and Surgeons. The accommodations are excellent, but the North River and Tenth Avenue are still rather out of the world.

St. Francis Hospital, New York.—A competitive examination for junior assistant will be held at the hospital, Tuesday, March 26th, at 11.30 A.M. For particulars address Dr. G. M. Edebohls, Secretary of the Medical Board.

A Society of Forensic Medicine has just been formed in Belgium.

The First Idiot Asylum in Italy.—An asylum for idiots has recently been opened at Chiavara (Liguria). This institution is the first of the kind established in Italy.

Dr. David Ferrier has been appointed Professor of Neuropathology in Kings College.

Gift to a Hospital.—Mr. John H. Converse, of Philadelphia, has given $60,000 to the Presbyterian Hospital of that city.

The Last New Treatment for Diphtheria is put forth by Dr. Arthur Hennig (*Berlin. Klinisch. Woch.*, February 18, 1889). Lime-water and ice-bags are the sovereign remedies against this pest of mankind, as it occurs at Königsberg, Germany.

Yellow Fever is stated to have broken out at Versailles, and to have numbered thus far four victims. It is suspected that the disease has been imported from South America by means of parrots, whose plumage may have harbored the contagium.

An Accommodating Medical Society.—The members of the Philadelphia County Medical Society are informed that any member who has an appointment to read a paper before the Society will have it set up in type and two galley-proofs furnished him on or before the day of the meeting, provided his copy is placed in the hands of the editor of the "Transactions" at least a week before the time it is to be read. If our County Society would help its members in a similar way, the plan would, no doubt, become popular.

Publishing Lectures without Permission of the Author.—On January 7, 1889, Judge Allison made a decree in Court of Common Pleas, No. 1, making perpetual the injunction which restrains Walter B. Saunders, a publisher of Philadelphia, from publishing and selling books on general and medical chemistry made up of condensations from lectures delivered at the University of Pennsylvania by Dr. Theodore G. Wormley, Professor of Chemistry and Toxicology in the Medical Department of that institution. The defendant is ordered to pay the costs of the suit.—*Medical and Surgical Reporter.*

A Proposed New Laboratory and Gymnasium for the Harvard Medical School.—At a special meeting of the faculty of the Medical Department of Harvard University, held on February 23d, it was announced that Dr. Henry F. Sears had offered to present the school with $40,000 for the purpose of erecting a pathological and a bacteriological laboratory. The matter was referred to a special committee. The plan proposed is to build a two-story annex to the present building, one story to be devoted to pathology and the other to bacteriology, and to fit up a gymnasium for the students in the basement.

Successful Removal of a Cerebral Tumor.—The first operation of this kind ever done in France was performed recently by Professor Pean. The patient suffered from Jacksonian epilepsy, and the tumor causing it was located in the upper motor region of the cortex by MM. Ballet and Gelineau. The patient is said to have been cured.—*Gazette des Hôpitaux*, No. 22, 1889.

Forty Thousand Anæsthetizations with Chloroform without a Death.—At the distribution of the prizes to the students of the Hyderabad Medical School, by the Duke and Duchess of Connaught, on January 25th, Surgeon-Major Lawrie, M.D., Principal of the Medical School, in a short address, referred to the commission appointed by the Nizam's Government to make experiments with reference to the effects of chloroform. This commission performed hundreds of experiments on dogs, and never found that the chloroform narcosis affected the heart until after respiration stopped. "This," adds Dr. Lawrie, "tallies exactly with my own experience. I have given chloroform as often, or oftener, than any man living, and have never had a fatal case; and I can state positively that in the 40,000 or 50,000 administrations I have superintended, I have never seen the heart injuriously or dangerously affected by it. I take no credit to myself in this matter. I have simply carried out in India the principles Simpson and Syme practised and taught in Edinburgh." In the hospitals attached to their school, chloroform was invariably given with absolute, or, he might almost say, with guaranteed safety by students, and they were never allowed to examine the heart beforehand, or feel the pulse during its administration. Chloroform seems to be especially well adapted to the Indian climate.

Lead-poisoning from Chrome Yellow used as a Cake Dye.—Dr. David Denison Stewart has collected seventy-nine cases of poisoning from the eating of cake dyed with chrome yellow. He says (*Medical News*): "It is to the point, in this connection, to state that I believe I can trace to lead-poisoning from dyed cakes many cases of disease of seemingly obscure or supposed idiopathic origin, seen in the past year and a half of my service in the out-patient medical department of the Jefferson College Hospital. Among these are cases of pronounced anæmia, renal fibrosis, peripheral neuritis, spastic paralysis, neurasthenia, obstinate headache, and, at least, one case of long-standing delusional mania." The popularity of sponge-cake in Philadelphia is on the decline. Dr. Stewart's latest report shows that it may cause heart disease and paralysis agitans.

Hardy's Method of Treating Itch, as carried out at the Hôpital St. Louis, is as follows: The patient is first of all subjected to friction with black soap and water for about twenty minutes. Then he is placed in a warm bath for an hour, during which he continues to rub himself and to soap himself. On coming out of the bath he is again rubbed over the whole surface of the body for twenty minutes, with a modified formula of Helmerich's ointment. This treatment lasts for an hour and forty minutes. Rubbing with black soap and the bath aim at cleansing the skin, softening the epidermis, and opening the fissures, and thus preparing for the action of the ointment which is intended to destroy the acari. After this treatment the patients dress themselves without drying the skin, and are advised not to remove the ointment for at least four or five hours. This prolonged contact is intended to insure the destruction of the acari, and especially to reach those which may have wandered on to the clothing; the individual who is thus covered with sulphuro-alkaline ointment is a veritable fumigating machine, exhaling sulphurous vapors. Nevertheless, to insure cure and to prevent the itch from being reproduced by the acari remaining in the clothing, it is better to pass through the vapor of sulphur the clothing which has been worn from the beginning of the disease, and completely to change the linen and sheets, and to burn any gloves which may have been worn.

A Large Fee.—A wealthy sugar manufacturer of Odessa, who died recently of typhoid fever, not being content with the five Odessa practitioners who were in attendance, sent first to Kief, for Professor Trichel, and finally, a few days before he died, to Vienna, for Professor Nothnagel, for whom a special train was ordered. It is stated that the fee given to the eminent Austrian professor was £1,500.—*The Lancet.*

Hunterian Orations.—There are various methods of securing medical or surgical immortality and of preserving one's name in perennial freshness throughout the lapse of years. None, however, is so practically and insistently effective as that of establishing a fund for an oration to be delivered annually upon one's life and character. Among the literary, oratorical, and scientific events of the year in London, for example, is the Hunterian Oration. Every season some new candidate is chosen to revive the memory of John Hunter and adorn it with the flowers of oratory, or the more sombre garments of philosophical reflection. It is interesting to note the ingenuity of successive orators in dealing with their subject. One year John Hunter is a great surgeon; the next year he is unsurpassed as a physiologist; and then we have him as a philosopher, a man of science, and a general practitioner. It is a good thing to be reminded of departed greatness, and to have such rugged and noble types as John Hunter occasionally brought to our attention. But we fear that our English brethren, under their perennial Hunter and Harvey orations, will, by and by, lose their feeling for true historical relationships, and think that ancient medicine was a binary compound of William Harvey and John Hunter. The facts are, with regard to Hunter, that his annual orators make ridiculous claims as to his influence on the development of surgery. He made no path-breaking discovery, and instituted no extraordinary revolution in surgical thought or method. He gave a tremendous impulse to scientific inquiry and better surgical methods, but such progress was part of the times, and was bound to come. There were great men before Agamemnon, and we should be glad if our London medical orators could in some years tell us about other not less notable worthies of medicine.

The Intercolonial Medical Congress and Disease in Australia.—The second Intercolonial Medical Congress was opened auspiciously at Melbourne, on January 7th. An address of much interest was delivered by Mr. T. N. Fitzgerald, President of the Congress (*British Medical Journal*). He said that in Australia there were three thousand medical practitioners, educated and trained in the same way as European medical men, and representing most of the schools in Great Britain and on the Continent. The conditions of life, he continued, in these colonies were different to what they were in the old country, and Australasia presented a new and wide field for medical and surgical observation. Although our habits and the conditions under which we lived bore a social similitude, yet they were by no means identical with those existing in Europe. The description of the sweating system was an incomprehensible revelation to the native-born of these colonies. With us food was plentiful and the hours of labor short, and summer and winter were much the same. The heat might at times be oppressive, but it could never be said to be unbearable or inimical to life. The causes which produced scrofula and tubercle existed here but to a slight extent, yet scrofulous impregnations were excessively virulent; while phthisis was as common with us as it was in England, and decidedly more so than in Canada and Scotland. The tertiary ulcerative forms of constitutional disease were comparatively mild affections here, and seldom presented that grave character which was such a continual source of anxiety to the European practitioner. Skin diseases were, however, not rare. Melancholia was a common form of insanity in our asylums. Alcoholic intemperance, tubercular deposits, and typhoid fever—scourges in the main preventable—swelled our mortality bills. Habitual drunkenness was an exception; but alcohol was not suited to our climate, for hepatic and renal troubles were sooner engendered by its use than in a colder country. Of the gravest consideration was it to discover how, in a country so richly endowed and with a climate so genial, we should yet be afflicted to so terrible an extent by two diseases such as typhoid fever and phthisis, both of parasitic origin and both eradicable. We seemed unable to cope with typhoid. Streets were marked out and houses were built without the semblance of drainage. Then when the warm weather came the fever stalked each year, more viciously and greedily than before. The colonial love of outdoor life and athletics developed muscular fibre, physical courage, and good temper.

Obituary.

JAMES W. RANNEY, M.D.,

NEW YORK.

Dr. James W. Ranney, of this city, died on February 26th, in the sixty-fifth year of his age. He was born in Townshend, Vt., in 1824, and received his early education at Middlebury College. After he left Middlebury College he came to New York, and was graduated from the Medical College University. He went back to Vermont and began the practice of medicine in Bennington. The prospect of a larger income soon induced him to come to this city, and about 1853 he first established himself here.

Politics had some charm for him, and within a year after his arrival in New York he was elected a member of the Common Council, which position, owing to the rapidly increasing number of his patients, he was soon obliged to resign. In 1860 he was elected Coroner, and served as such for three years.

Dr. Ranney made lunacy something of a specialty, and for almost twenty years, up to the time of his death, he was Lunacy Commissioner in this city. In almost every case of note of that character which has occurred here within eighteen or twenty years his opinion has been sought.

In the struggle between the Rev. John P. Newman, Pastor of the Madison Avenue Congregational Church, and his rebellious flock, Dr. Ranney took an active part, being violently opposed to Mr. Newman retaining charge of the church.

Dr. Ranney for twenty years has been surgeon and attending physician for a dozen or more railroads, and has done much valuable work in adjusting suits for damages against those roads with which he was connected. He was a Mason, a member of the County Medical Society, and a Fellow of the Academy of Medicine, and for a number of years had been physician for the Society for the Prevention of Cruelty to Children.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, February 1, 1889.

F. P. KINNICUTT, M.D., PRESIDENT, IN THE CHAIR.

DR CLEMENT CLEVELAND read a paper (see p. 261) entitled

STRETCHING THE SPHINCTER ANI AS A MEANS OF CURING CONSTIPATION.

In the discussion which followed,

DR. R. F. WEIR said that he did not quite understand how so slight an operation could have so striking an effect. He added that the mode of stretching the sphincter was an important matter. The old method of introducing the thumbs and stretching until they touch the tuberosities of the ischium, he had abandoned long ago. The better way was to stretch the sphincter in all directions.

Another point is that it is often wise to stretch the sphincter more than once, and in cases of fissure of drawing the knife across the fissure and severing some of the fibres.

DR. CLEVELAND said that his method of stretching was the same as that referred to by Dr. Weir.

DR. A. H. SMITH asked if the sphincter ever became exactly the same as before the stretching.

DR. WEIR thought that sometimes it did, and sometimes it did not.

DR. KINNICUTT had seen in children a hypertonicity of the sphincter ani, and he had thought that the accompanying constipation might be benefited by stretching the muscle.

DR. WEIR said that he recalled similar cases in which he had to assume that there was a fissure, owing to the hypertonic condition of the sphincter, but in only one case could he find it. Here there might have been simply a spasmodic condition.

DR. HUNTER said that he had never seen a case in which the sphincter failed to contract as firmly as ever a few weeks after the operation.

DR. GEORGE L. PEABODY presented a specimen of

ENORMOUS GASTRIC ULCER, WITH GASTRITIS.

The patient from whose body was removed the stomach that I show you this evening was a native of the United States, R. S—— by name, thirty years of age, and a taxidermist by occupation. He was admitted to the New York Hospital on September 10, 1888. He gave no morbid family history; he had been a beer-drinker for years, but had been totally abstinent during the previous three months. He had never had rheumatism or malarial fever. Ten years ago patient had a venereal sore, followed by suppurative adenitis, but no further symptoms. For three years patient had been been troubled with flatulence, water-brash, borborygmi, constipation, and epigastric pain after the ingestion of food. One week ago patient vomited blood, during a single forenoon, to the amount of two pints. The previous night he had taken a dose of salts. He knew of no cause for the hemorrhage. Since that time he had eaten regularly, without pain or inconvenience. He eloped after thirty-six hours, before any plan of treatment could be efficiently tried.

On October 30th he returned. Since leaving the hospital he has had constant epigastric pain. Pain is increased by the ingestion of food and vomiting is frequent, the vomited matter having a black color and apparently containing blood. Constipation is the habit. Movements are small, dark-colored (brown), and very hard.

Emaciation has been rapid during the past four months. Temperature, 99°; respiration, 24; pulse, 100.

His appetite, he says, is good.

Physical examination.—No cardiac or pulmonary lesion. Superficial hepatic area is enlarged, extending from fourth rib to a point one and one-half inch below the free border of the ribs. Splenic area is normal. There is marked abdominal tenderness on pressure, most acute at the junction of mammillary line and costal cartilage. No tumefaction can be felt. Patient is emaciated and anæmic. On October 31st he was put upon peptonized milk and infusion of condurango.

Urine.—Yellow, alkaline, 1.020. Mucus and phosphates. No albumen. Negative microscopically. His weight is ninety-five and one-half pounds.

November 1st.—Vomited matter was tested and found to contain no free Hcl. Vomiting is persistent. Brandy and nutritive enemeta ordered.

Complains of constant severe epigastric pain.

November 5th.—Daily washing of stomach with gastric syphon was commenced. At the first washing two quarts of fluid were withdrawn from stomach before irrigation could be begun. His pain has become so constant and severe that morphine is now given regularly at night, subcutaneously, one-fifth of a grain in quantity.

November 8th.—Weight, ninety-three and one-half pounds. Urine, amber, acid, 1.010, no albumen. Hyaline and granular casts. Urea, eighty-five gr. daily. Quantity, thirty ounces.

November 12th.—Acid. Dil. Hcl. ℥ xx.—t.i.d. Powdered pepsin, gr. xx. t.i.d.

November 17th.—Weight, ninety-seven pounds. Larger quantity of food is retained and epigastric pain is less severe. Diet consists of milk, eggs, and meat, which are borne well and apparently digested by aid of Hcl. and pepsin.

November 20th.—Patient has five diarrhœal movements daily. They are dark-brown in color, unformed, and of foul odor. Lead and opium pill, j., t.i.d., ordered.

November 24th.—Diarrhœa still present. Opium suppositories and powders of morphine, bismuth, and camphor have all failed to check it.

December 3d.—Patient is losing strength and becoming more emaciated daily. Stomach is very irritable and little food can be retained. At this time all medication addressed to the stomach was suspended. After the lapse of two weeks lavage was again begun, and he was then given trial meals consisting of protein substances. After the lapse of an hour or thereabouts the stomach-contents were removed by tube and tested for free hydrochloric acid, by the phloroglicin-vanillin test. The result showed no evidence of the presence of free hydrochloric acid. Diarrhœa is still unchecked. Hypo. Magendie, ℥ viij. is now required, q. 12 h.

There is an increased sense of resistance in the epigastrium at the right of the median line, but no tumor.

Lavage become again very painful to him, and after two such tests as that just described, with an interval of several days between them and with similar results, it was abandoned.

December 7th.—Patient is now suffering from catarrhal bronchitis and laryngitis. Vomiting begins almost immediately after effect of morphine wears away.

December 15th.—Marked œdema of the feet and ankles is present. A small abscess is forming in the right inguinal region.

December 18th.—Abscess opened and creolin dressing applied.

December 29th.—Patient has grown rapidly weaker, and has required narcotism to relieve his suffering. He has taken little food. Bronchorrhœa has become very marked, and there is apparent inability to expectorate mucus. Breathing became labored and shallow, and heart failed; at 2.50 A.M. he died. P.M. Temperature, 98° F.

Autopsy.—Organs normal, except as below.

Peritoneum contains three pints of milky fluid. Upper surface of stomach and under surface of liver are united by old adhesions; mesenteric glands enlarged;

kidneys showed signs of not very advanced chronic diffuse nephritis; stomach contained three pints of partially digested food. An ulcer is found involving entire length of lesser curvature to within half-inch of œsophagus, and extensively involving also the anterior and posterior walls of stomach. Ulcer measures along lesser curvature four inches, at right angles to this measurement seven and a half inches. Bottom is smooth, edges thickened, and undermined to a distance of one and a half inch in places. Ulcer is apparently healed. Through the base the under surface of liver is distinctly seen; mucous membrane of rest of stomach is thickened, and obviously in a condition of advanced chronic gastritis. Liver small, centres of acini pigmented; large gut also pigmented.

Microscopic sections, which Dr. James has been kind enough to make for me from different portions of the stomach, show it to be very extensively changed. No gastric tubules are visible, the whole thickness of the mucous membrane being invaded by myriads of young cells, which have made them unrecognizable. Indications of their former presence can be detected by a sort of arrangement of epithelium in parallel columns.

The interest in the case centres in the few symptoms of carcinoma that the patient manifested—constant pain, emaciation, intense anæmia, and death—as well as the absence of free hydrochloric acid; and also in the problematical etiology of so large a gastric ulcer as this—certainly the largest I have ever seen. The fact of his occupation, as a taxidermist, is of interest; may his frequent handling of arsenic have had to do with his malady?

Dr. Kinnicutt, in the discussion, said that an absence of free hydrochloric acid in such a case as had been described by Dr. Peabody, should be expected. There had been an extraordinary loss of the secretory structures of the stomach by ulceration, and Dr. Peabody had stated that the gastric tubules were with difficulty found in the mucous membrane which had escaped destruction. A positive diagnosis in Dr. Peabody's case seemed to him impossible.

Dr. J. West Roosevelt presented the history of a case of

CANCEROUS STRICTURE OF THE PYLORUS WITH DILATED STOMACH.

The point of interest had been the great difficulty of diagnosis on account of the peculiar position of the stomach.

Dr. Roosevelt referred incidentally to the fact that the

HEART APEX

was in the fourth intercostal space, instead of the fifth. He had observed this position of the apex in a number of cases of normal hearts.

Dr. Kinnicutt said that in very young children the apex beat, as a rule, was found in the fourth space, in or just outside the mammillary line. In adults, he thought there was no reason to believe that the location usually given, the fifth space within the mammillary line, was incorrect. In health, it might vary slightly, temporarily, from distention of the stomach.

Dr. Hunter, referring to the subject of stomach dilatation, reported a case of

ACUTE DILATATION OF THE STOMACH

after an ovariotomy. The dilatation came on within ten days after the operation, and it was not present when the abdomen was opened by the surgeon. The patient died, and the post-mortem showed a stomach filling the whole abdominal cavity.

Dr. Kinnicutt reported a case of

SPONTANEOUS DEPOSIT OF CHOLESTERIN IN THE URINE.

It had been shown that the oily particles so frequently seen in the urinary deposits of chronic Bright's disease often contained cholesterin in a dissolved state. The spontaneous deposit, however, of cholesterin crystals in urine was of extreme rarity.

He had recently found the crystals in great numbers in the urine of a patient with the following history. Mr. D—— had very recently been under his care, suffering from an acute attack of gastro-duodenitis. There was moderate jaundice, white stools, and on the second day of the illness a trace of albumen appeared in the urine, with casts both granular and hyaline, and biliary coloring matter. On the fourth or fifth day from the onset of the attack, very numerous cholesterin crystals were discovered in the urine, the examination being made a few hours after its voidance. The albumen, casts, and biliary matters gradually disappeared, but the cholesterin crystals continued to be found for several days after the complete disappearance of the former. The urine at the present time was quite normal in character.

Aside from the interesting phenomenon of the spontaneous deposit of cholesterin crystals, the occurrence of numerous casts, both granular and hyaline, in the urine of such cases as the above, was worthy of attention. The possibility, even the probability, of such a temporary morbid phenomenon in cases of retention jaundice, should be borne in mind.

The patient whose case had been narrated, had been under his observation for a number of years, and had never shown any symptoms of renal trouble. His urine had been examined two days previous to the above attack, and had been found to be normal in character.

Dr. Robert F. Weir presented specimens of

PHOSPHATIC CALCULUS REMOVED BY SUPRA-PUBIC SECTION FROM A MAN SEVENTY-NINE YEARS OF AGE.

The special points of interest were these: 1. The successful result of a cutting operation at an advanced age. 2. The ease which the clawing or rake-like action of the fingers gives in drawing the subperitoneal fat from behind the pubis upward, and in this way quickly and safely exposing the bladder without hemorrhage, after splitting the recti muscles in the median line, instead of cutting or tearing through the tissue. 3. That a drainage-tube was used with lateral decubitus for three days, and that the bladder opening closed in twelve days. 4. That iodoform mania resulted from the packing of the wound with a ten per cent. gauze.

It may be added that litholapaxy was abandoned after an ineffectual trial with the lithotrite, on account of a large pedunculated median prostate hypertrophy. The calculus weighed one hundred and eighty grains.

Belladonna in Shock.—Dr. William B. Bradner, of Warwick, N. Y., writes: "Dr. Cheever gives many excellent directions in answer to the question as to what we can do to relieve shock, but it seems to me that he overlooks one most valuable remedy, viz., belladonna. For over a quarter of a century I have used belladonna or atropine either to prevent shock, or to hasten reaction during shock. I usually give to adults $\frac{1}{60}$ grain of atropine hypodermatically, repeated if necessary, either with or without morphine, as the individual case seems to demand. To me atropine is an agent of the greatest value to hasten reaction, as its employment will often give a healthy glow from the death-like pallor, and a sense of increasing warmth for the cold surface."

The University of Lausanne.—The authorities of the Canton of Vaud, Switzerland, have decided upon the establishment of a university at Lausanne. A great impetus has been given to the work by a gift of $600,000 from a wealthy gentleman, M. Rumaise, with the specification that it be devoted to the advancement of higher education in the canton. The personnel of the medical faculty is said to be excellent, and clinical material is abundant, owing to the fact that a preparatory medical school, annexed to the faculty of sciences, has been in existence in Lausanne for over four years.—*Lyon Médical.*

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, February 25, 1889.

ALEXANDER S. HUNTER, M.D., PRESIDENT, IN THE CHAIR.

THE VALUE OF WATER IN MODERN THERAPEUTICS; A CLINICAL STUDY OF THE METHODS OF APPLICATION IN VARIOUS DISEASES, AND THEIR RESULT.

AT the last stated meeting of the Society Dr. Simon Baruch read a paper with the above title, and at its conclusion the Society voted to make its discussion the special order of this meeting.

DR. A. JACOBI sent a written communication, which was read by the Secretary. The subject, he said, was by no means new in medical literature; not even in American literature. He had used cold water extensively some dozen years, not only as a local application in inflammatory local swellings, but for the purpose of stimulating the circulation and reducing increased temperature. Among the most conclusive accusations raised against him, in an institution from which he succeeded in getting himself expelled nearly twenty years ago, when he was president-elect of the County Society, was the charge that he was guilty of using cold water in the treatment of sick children. This injurious consequence of its use in his case was evidently not attributable to the physiological action of water.

Dr. Jacobi referred to some of his papers on antiphlogistics published in THE MEDICAL RECORD, 1870, in which he urged the occasional use of cold water in scarlatina, variola, asphyxia, lobar pneumonia, acute heart disease, according to the methods so vividly described by Dr. Baruch, besides its local application in adenitis, local peritonitis, ophthalmia, etc. But at that early time he added that cold water was no panacea or remedy suitable for every age and condition. It might do harm. A baby should not have a really cold bath until it had developed the faculty of locomotion and the reactive power that came with it. On the use of water, particularly cold water, in the treatment of diphtheria, he had expressed his views in his treatise on the subject in 1880. In a paper published in THE MEDICAL RECORD, 1875, he urged the use of cold water as the principal antipyretic in typhoid, and also in another paper published in the "Archives of Pædiatrics," 1885. But in speaking of the use of water we were apt to think of it as cold. We should not, however, forget how beneficial it might be when hot. Hot water in many cases of gastric catarrh, hot water injected into the bowels in intestinal catarrh, in dysentery, and in general collapse, also the hot pack, were too beneficial to be overlooked.

DR. S. HENRY DESSAU thought there were a few places for the use of water which had escaped Dr. Baruch's attention. Water served an excellent purpose when given to infants as a drink when they cried for milk before meal-time. Notwithstanding that much had been said on the subject of recent years, infants were still much more likely to be overfed than underfed. The human race would grow up healthier if, instead of giving the infant milk every time it cried, pure water were given until sufficient time had elapsed between meals. Cold water in summer diarrhœa not only served to allay heat and dryness of the mouth, but supplied a want of nature created by the excessive intestinal discharges. He also believed in giving cold water plentifully as a drink in scarlatinal nephritis. The daily bath in infants was the best nerve-tonic. It should be begun at the fourth or sixth month of age. At the end of the first year the bath could be of about 70° F., and in the summer of the normal temperature of Croton water. Gently and gradually submerge the infant. The proper treatment of laryngismus stridulus was application of cold water. In infantile convulsions occurring during the course of fever he used cold bath or wet sheet; if the convulsions were due to peripheral irritation, as dentition or overloaded stomach, he used the hot bath. He had also employed cold water in chronic diarrhœa of infants, as recommended by Dr. Messemer, and hot water enemata with a small quantity of bicarbonate of soda in sciatica of adults believed to be due to proctitis.

WATER HYPODERMATICALLY FOR THE RELIEF OF PAIN was also a procedure employed by Dr. Dessau with speedy and almost uniform success. It was, however, best adapted to the relief of pain of neurotic rather than of inflammatory origin, as in neuralgia, lumbago, sciatica, etc. It was injected neither cold nor warm, but at ordinary temperature.

DR. VINCENT ZOLNOWSKI agreed with Dr. Baruch and Dr. Dew regarding the physiological principles involved in the use of water, and also that the remedy was powerful for evil as well as for good, and its use should ever be guided by judgment. In every case a careful chemical and microscopical examination of the urine should be made, the lungs and heart auscultated, the liver examined, before determining upon the special character of hydropathic therapeutics to be employed. The treatment, even in the same person, should vary according to the condition of the circulation, the temperature, age, vital resistance. The atmospheric temperature should have its weight in deciding upon the degrees of cold or heat required. The remedy should be used on the judgment of the physician, and not on the caprice of the nurse or patient. Full baths, half-baths, douches, sprays, packs, sitz-baths, etc., were all good when properly applied, but all should be used with judgment and discretion. The physician who had proper physiological knowledge would attain the same result by different applications of the same simple, single remedy.

Water could be used as an antiphlogistic, sedative, excitant, tonic, derivative, and solvent; but the two general methods to be observed were its use as an excitant, or as a depressant. As an excitant it should be used quickly, and the degree of temperature proportioned to the degree of irritability to be overcome. The less the irritation, the lower the temperature used. The withdrawal of heat from the economy should be small in amount and correspond to the rapidity of its formation. It should be combined with friction of the surface.

The nervous system could be brought actively into play by hot fomentations, dry packs, or wet packs of long duration, followed by a cold half-bath of low temperature, a douche, or shower-bath of a few minutes' duration, succeeded by rubbings. With this method the active movement of the muscles was especially recommended to restore warmth.

The depressant method was of two qualities, antiphlogistic and sedative. In the antiphlogistic plan the heat should be withdrawn slowly, for by its sudden and rapid abstraction the nerves became irritated, reaction took place, and the changes in the deeper tissues were thereby increased. Moderate temperatures in such cases were to be used only until excitement was allayed, then lower ones applied. The temperature should be taken every two hours, and the process of half-baths, wash-offs, etc., repeated at every indication of a rise of temperature. The sedative method was recommended when the nerves were greatly excited. The low temperature was from 43° to 54° F.; the medium, 54° to 65° F.; the tepid, from 65° to 80° F.

The internal use of water as drink and enema acted mechanically. The author described some cases, the first being one seen by a number of eminent physicians in New York, who called it scleroderma. The man had during his life been troubled with disturbances of digestion, and constipation alternated with diarrhœa. In February, 1886, he began to have stiffness and pain in both shoulders and arms, and by April it had spread over the entire body, with great rigidity of abdomen, face, and neck, eyelids, cheeks, etc. The urine was 1.032, no albumen,

no sugar, loaded with urates. His weight had fallen from two hundred and nine to one hundred and sixty-three pounds. All who saw the patient thought his condition would rapidly progress to a fatal issue. Following the advice of the consultants, he first used electricity and gave arsenious acid; then had recourse to hydropathy alone, consisting in hot fomentations over the rigid parts, followed by half-baths of low temperature; massage with frictions of lanolin, subsequently of goose grease, which proved best. After pain disappeared hot fomentations were omitted, and warm baths of 105° F. employed, followed by douches of low temperature. At present pain had entirely ceased, and the hardness had become confined to the fingers.

The next case was one of extreme morphine habit, in a practising physician, who was cured by hydropathy in three months. The treatment consisted mainly of a cold falling douche over the head and spine, and for tympanites he wore constantly a wet bandage around the abdomen, and for insomnia at night, cold bandages from knees to ankles.

The next case was one of chronic articular rheumatism of long standing, the legs being moved by pulleys. He had been cured, and had had no return of the trouble for seven years. The next was one of marked neuralgia of left infraorbital nerve, cured in nine months. The cause of the neuralgia in this and two other cases was lithæmia.

Dr. August Seibert demonstrated the manner of washing out the stomach of infants, the method consisting in the introduction of a small, soft rubber tube down the œsophagus, allowing about half a pint of water to enter from a graduated measure connected with the tube by means of another rubber tube. The stomach was evacuated by siphon action, allowing the external end of the catheter to fall below the level of the stomach. One washing was usually sufficient to cure a simple disorder of the stomach arising from overfeeding, or where some of the food from one meal remained undigested to be mixed with the food of the next meal. In the next class of cases, those of chronic gastro-intestinal catarrh or enteric catarrh, a few washings, with regulated diet, would effect a cure. No medicines should be given. The third class took in cases of cholera infantum, twenty-eight of which he had had last summer, and cured twenty-six. The water employed was of a temperature of 104° F.

Dr. Ralph Parsons discussed the use of water in mental and nervous disorders. Its beneficial effect was not more striking than in some cases of maniacal excitement. Here the prolonged hot-bath was indicated, increasing in temperature from 95° to 105°, or even 110° F. But if prolonged several hours the temperature should be warm rather than hot. The head should be kept cool. This bath was indicated only in the strong. The warm bath at bedtime was often good in insomnia. Patients depressed physically and mentally were often benefited by the cold bath followed by manipulation. Proper reaction was more likely to follow the cold plunge or shower, when taken willingly, than when taken unwillingly or given by surprise.

Dr. Van Valzah pointed out certain precautions in the use of water, particularly in gastric and intestinal disturbances, and said that hot water promoted downward, while cold water favored upward, peristalsis. In catarrh of the stomach the water should be given, internally, an hour and a half before meals. A moderate amount of hot water stimulated thirst, more than the same quantity of cold water, in diabetes. A good indication as to the amount of water to be taken was the condition of the urine. This should be kept at about 1.016 to 1.018, and be not too high colored.

Dr. Wallian emphasized the fact that fever was a symptom, not a disease; that disorders of the human economy arose from overburdening certain organs, and failure of elimination of waste elements. The physician's duty was not simply the administration of drugs to cure disease, but to restore function by aiding elimination and correcting errors of living. The chief agent in elimination was water, and he deprecated the craze for antipyretic drugs in the reduction of the temperature. The weight of athletes had been reduced as much as six pounds in two hours by hastening elimination through the skin. Nothing was better in promoting the function of the skin than water. He did not believe cold water should be substituted for hot water in the treatment of typhoid.

Dr. W. F. Holcombe described the great benefit derived from the internal use of water and the meat diet in Bright's disease and gastritis, in his own person, and said that he had acquired the power, which he thought others might do, of evacuating the stomach at pleasure by regurgitation.

Dr. Hungerford, of Connecticut, gave an unfavorable experience with the treatment of gastric catarrh, in his own person, by the method just described by Dr. Holcombe.

Dr. Baruch made the final remarks, and referring to Dr. Jacobi's statement that cold feet contraindicated the use of cold water, said he disagreed with him, but means should be taken after its use to bring about reaction.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

A CASE OF ACTINOMYCOSIS HOMINIS—PASTEUR'S BRITISH PATIENTS—THE TRUE DEATH-RATE AMONG PERSONS BITTEN BY RABID DOGS—THE VOTES OF CENSURE ON SIR MORELL MACKENZIE—SIR MORELL MACKENZIE'S REJOINDER TO THE COLLEGE OF PHYSICIANS.

London, February 16, 1889.

The last meeting of the Medical and Chirurgical Society was entirely occupied in discussing the subject of actinomycosis. The discussion was introduced by a joint communication from Dr. Douglas Powell, Mr. Godlee, and Mr. H. H. Taylor, in which the history of a case of actinomycosis hominis was given. The patient was a boy, nine years of age, the son of a dairyman, who was admitted into the Brompton Consumption Hospital, under the care of Dr. Powell. He had been ill for four months, and had suffered from hectic symptoms, slight cough, and painful swellings on the right side of the chest; there was a family history of tubercle. The symptoms observed on admission were irregular fever, emaciation, and slight cough, attended with pain in the right chest. The physical signs noted were: enlargement of right chest, with local swellings, elastic and painful in the infra-mammary and lower postero-axillary regions; complete dulness over lower two-thirds of right chest, with annulled respiration, and vocal fremitus, and weakened voice sounds; displacement of heart, a short bruit being heard at the base; liver and spleen normal; slight enlargement of glands in right axilla and neck. Empyema was suspected, but no pus found on exploration. Fluctuation having occurred in the lower swelling, the latter was incised, and a further exploration of the pleural sac made. As the result, some semi-solid matter mixed with blood was removed; on examination, this proved to be a degenerated tissue teeming with the ray fungus.

Professor Crookshank gave a morphological report of the actinomyces fungus obtained from the case, and demonstrated that the supposed two varieties met with in man were in reality one and the same. Dr. John Harley remarked that he did not yet consider it as finally settled whether the micro-organism was the cause or the concomitant of the disease. Mr. Eve observed that Dr. Powell's remark that the present was the first case diagnosed in England during life was hardly correct, since he had himself published a case more than a year ago of

actinomycosis affecting the liver; the diagnosis was made during life, and subsequently verified by post-mortem examination. Dr. T. D. Acland thought it was probable, from what they had seen among the many specimens exhibited that evening, that when the disease was luxuriant it might be that the fungus was polymorphous. His English specimens, when shown to Israel and Koch, seemed to them quite anomalous, and it was worth consideration whether the fungi, as seen in England, and in Germany, were really of the same species. Dr. Markham Skerritt referred to a case of actinomycosis which had been under his care in the Bristol General Hospital in 1886. The patient was a man, twenty-eight years of age, and had nothing to do with cattle, being a house-decorator. The temperature chart showed large, irregular, daily oscillation, as in that exhibited by Dr. Powell. There were pulmonary and pleural symptoms at first, but the growth having penetrated the diaphragm and invaded the liver, the pulmonary symptoms became unimportant. After death, the lung was found to have become a structure of dense fibroid tissue, and the growths in the liver looked to the naked eye just like the actinomycosis of cattle. Dr. Skerritt said the disease would probably be found to be much commoner in men and cattle than was now supposed. Dr. Powell, in replying, acknowledged that he had overlooked Mr. Eve's paper, but said he had only claimed that his own case was the first in this country in which actinomycosis of the *lung* had been diagnosed during life. Mr. Godlee said the paracentesis for supposed empyema had done harm rather than good; the growth was very vascular, and when a small portion of rib had been excised, the boy would probably have died at once, if they had not had at hand means for quickly plugging the wound. The enlargement of the superficial veins round the tumor was remarkable, and indicated pressure, not only on the azygos system, but also on the superior and inferior venæ cavæ. Professor Crookshank discussed the microscopic characters of the specimens in several of the cases. In the German cases there was some variation in staining, which led him to think the organism was probably polymorphic. He considered actinomycosis was a common disease in cattle. Many cases were mistaken for "perlsucht;" many were disregarded. In man, also, some cases were probably overlooked.

From a return issued by the Local Government Board, it appears that 85 British subjects have been treated by Pasteur during the past two years. In 24 cases the dog was proved to have been rabid by the experimental test; in 44, the dog was recognized to be rabid by the veterinary surgeon; and in the remaining cases (17), the dog was only suspected of being rabid. In 4 cases the patient afterward died of rabies, and in 1 case died of rabies while under treatment. Professor Horsley, in a communication just made to the Epidemiological Society, states that the death-rate among persons bitten by dogs undoubtedly rabid averages fifteen per cent., and points out that in the same class of patients Pasteur has obtained a death-rate of only 1.36 per cent. Professor Horsley therefore regards the success of Pasteur's treatment as assured.

Sir Morell Mackenzie's book on the late Emperor Frederick continues to excite many comments. The author has been censured both by the Council of the College of Surgeons, and by the Fellows of the College of Physicians in Comitia assembled. Although Sir Morell Mackenzie lately resigned his membership of the latter college, the Registrar was directed to forward him a copy of the resolution of censure. A reply was received from the secretary of Sir Morell Mackenzie, to the effect that the latter took no interest whatever in the proceedings or opinions of the College of Physicians, and requesting Sir Henry Pitman, as the Registrar of the College, to desist from further intrusion upon Sir Morell Mackenzie.

To Quiet Crying Babies try a drink of water.

ELECTROLYSIS AND STRICTURE.

To the Editor of The Medical Record.

Sir: Drs. G. E. Brewer and W. R. Otis have published, in your issue of 23d ult., an open letter to Dr. Newman, in which they propose to settle the disputed point, as to whether "Electrolysis is of any value whatsoever in the treatment of organic urethral stricture, by having ten patients provided, five of whom shall be treated by his method, and the remaining five they will treat by dilating urethrotomy." These gentlemen should recollect that it has never been contended that dilating urethrotomy cannot produce a urethra of extended calibre, retaining such extension for a month or two; but, gentlemen of their school hold to the theory that electrolysis cannot be regarded as a curative agent in the treatment of organic urethral stricture. If, therefore, they desire that a strictly impartial investigation should be made by a committee of competent and impartial surgeons, let such committee submit the whole ten cases to Dr. Newman for treatment, and let them be examined after he reports them cured, and that will demonstrate without doubt whether or not his treatment is potent in its effects. Every one is aware that a urethra may be cut to the calibre of say 44 French, but the fact is not to be disputed that a urethra of 28 calibre, which will not contract after ten or twenty years, is all that is necessary. Nextly, the advantage claimed by electrical treatment is, that it is safe and pleasant; and surely any man will elect such if its results will be satisfactory, instead of submitting to a cutting operation painful in its character, attendant in some cases with considerable danger to life, and the recovery from which may entail weeks of confinement to the bed and house.

I repeat by way of emphasis what, according to the admission of Drs. Brewer and Otis is the disputed point, "Whether electrolysis is of any value whatsoever in the treatment of organic urethral stricture."

Your obedient servant,

A. D. C.

THE ABUSE OF ETHERIZATION—A PLEA FOR THE JUNIOR ASSISTANT.

To the Editor of The Medical Record.

Sir: The article on "Etherization," by Dr. Shrady, in The Record of February 23d, was timely, and full of good points. But wasn't he a little hard on the junior assistant? That individual, to be sure, has just graduated, but he has shown by his examinations that it was by his brains he obtained the position. The lot of the junior is not a pleasant one. He is the general subject for all the disagreeable duties of the house staff. He writes up the books; he analyzes the urine; he runs errands for the house and senior assistant; and, on top of it all, he has charge of the administration of the anæsthetics. The chances are that on his first day's duty he has this pleasant part to do. Is he assisted any by the other members of the staff? Not much—they enjoy his efforts to control the patient; they smile when he lifts the cone from the face for a few seconds, and remark one to the other, "He won't do that much longer: wait till he is pulled up by the 'visiting.'" They know it is coming, and consequently are delighted when the visiting surgeon remarks, in tones decidedly sarcastic, "Well, doctor, if you cannot get the patient under, let Dr. J. take the ether." Dr. J., the senior, steps up and, with a nonchalant air born from his six months' acquaintance with the cone, soon "drowns" the patient into insensibility. The next time the junior gives the anæsthetic he copies as nearly as possible the act of the worthy senior, and soon is an expert in "getting a patient under" quickly. Another thing that is conducive to this rapid method is the operating surgeon himself. How often does he rush in from an hour to an hour and a half late, and rush to the operating-room, with directions to the junior to hurry up and get the patient ready. Is it any wonder that the cone is pushed snugly over the nose and

mouth; that the doctor and all the available nurses sit on the poor creature who is down on the table? No; for the operating surgeon, the man whose word is law, has said "hurry up," and the junior is not going to have the honor taken from him if he can help it. Besides, he is on the look-out for the smile of approval which greets him if the patient does get under the influence of the anæsthetic quickly. Does this encourage the careful administration of ether in the junior's mind?

His troubles are not through yet, for every five minutes the house surgeon, on whose broad shoulders rests all the responsibility of the operation, even if his duties are not of that high order of things, inquires in stentorian tones, so as to be heard by all the assembled multitude, "How is she, doctor?" "Let up on the ether!" "A little more ether!" "Come, doctor, crowd your ether; she is going to vomit!" This, interspersed with orders directly the contrary from the operator, naturally confuses the unsophisticated man. Result—the patient, as a rule, comes out of the ether and begins to kick; a general rumpus follows; finally science conquers, and the operation is finished. I will not take up your valuable space with any more remarks on the subject, but let me add a few rules for the persons in authority:

1. Give the junior plenty of time to get the patient under the anæsthetic without "crowding."
2. Let the manipulator of the cone alone while the operation is going on, unless there is *need* of interference.
3. Give the patient a small hypodermic injection of morphine before the administration to prevent vomiting.
4. Do not imply that the junior is a fool, if the patient is not disposed to take the anæsthetic kindly.

A FORMER JUNIOR.

THE CAUSE OF RICKETS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: It would be very interesting to know what opinions are held by physicians in various parts of the United States of America, on the question of the etiology of rickets. So far as I have been able to form an idea from conversations with visitors to this country, it would seem that in America rickets is not a common disease. The same seems to be true of Australia and New Zealand. It is probable, however, that climatic conditions may have some influence in other countries as with us.

In *The Lancet*, December 6, 1888, I stated briefly my view that rickets is due to any cause which interferes with the function of respiration; and preferably to bronchitis, broncho-pneumonia, and pneumonia. This view was the result of the experience of many years' observation and careful attention to this particular question of what is the chief cause of rickets, and was founded entirely upon clinical data. The question is one that is not in a satisfactory state at present, and possibly there are physicians in America whose opinions upon it would be both interesting and valuable. Yours obediently,

ROBERT LEE, M.D.

EARLY OPERATION IN CASES OF TYPHLITIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In common, doubtless, with many other practitioners, I have been much interested in your recent report of a discussion on the subject of typhlitis and perityphlitis by the Northwestern Medical and Surgical Society of New York, and which followed the reading of an excellent paper by one of the members—Dr. Jacobus.

Not to comment upon the question of the pathology of these inflammatory swellings in the iliac region which engaged somewhat the attention of the speakers, and which, notwithstanding all that has been said, I believe to be still unsettled, I desire particularly to refer to the manifest leaning of several of them to a very early operation in these cases. Indeed, we find this recommendation earnestly made by more than one member who took part in the discussion, on the ground that suppurative peritonitis from perforation, which is almost certain to occur, may thus be forestalled. Nor, in their view, does a moderate constitutional reaction seem to preclude the performance of the operation, since pus may be expected early to be present without being heralded by the more pronounced symptoms which, oftener than otherwise, attend its formation elsewhere in the system. Consequently, the rule of action fairly deduced from the expressions of these gentlemen is, that an inflammatory process, more or less emphasized by the presence of a painful swelling arising suddenly in the region of the cæcum, and which may be justly considered to come within the definition of the term typhlitis, or perityphlitis, should, unless a decided amelioration of the symptoms soon occur—say after forty-eight hours—be subjected to prompt and radical surgical treatment.

Now, without reflecting upon the propriety of this rule, which may or may not be well-founded in practical results, I simply desire to say that I have seen at least four instances where the tumor in the iliac region was exceedingly well defined and attended by constitutional symptoms of a high grade, where resolution gradually took place under the rest, saline, and opiate treatment, no relapses following so far as I have ever heard. One of these cases I recently saw in the person of a youth, twenty years of age. The inflammatory swelling was so prominent as to attract the observation and apprehensions of the relatives, who came for me on this account. The right leg was flexed, there was fever (103°), and the swelling hard and very painful, the decubitus being constantly dorsal. Accepting Bartholow's advice, which I had followed in other cases, I employed the sulphate of magnesia for its osmotic effect; this being promptly secured, the exhibition of morphia and the tincture of aconite, in moderate but frequently repeated doses, was resorted to. Recognizing, with others, the great value of the ice-bag under these circumstances, I nevertheless preferred in this case to apply the hot pulverized flax-seed poultices, which gave great relief to the inflammatory tension and pain. At the end of a week or ten days the symptoms had practically disappeared; only a localized but painless hardening at the site of the inflammation, and which was certainly diminishing, remained. In the other cases I had a similar experience.

It is only right to add, however, that several years ago I lost a case by suppurative peritonitis, having its origin in a painful tumefaction of the kind in question, which might have been saved by timely and intelligent surgical interference. At an autopsy, also, which several years ago I made for a friend who had diagnosticated differently, I discovered suppurative peritonitis caused by perforation of an abscess that had formed in the vicinity of the cæcum. But where to draw the line in our dealings with this malady "is the riddle of the Sphinx," and I very much question if Dr. Wylie's brilliant success, or the opinions expressed in the discussion above mentioned, will solve it to the satisfaction of the average practitioner, who, after all, will have to judge for himself the symptomatic import of such cases, wherein he is invested with a grave responsibility. HENRY K. LEAKE, M.D.

DALLAS, TEX., February 8, 1889.

DISEASE COMMUNICATED FROM THE HUMAN TO THE LOWER ANIMAL.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Reading an article in a previous issue of THE RECORD from Dr. J. J. Chisholm, of Baltimore, giving an account of a case of measles in a dog, contracted from his young master, brought to my recollection a somewhat similar case. The event is very recent, occurring in my practice during the past year.

About four years ago a patient came under my care for treatment for scrofula. The disease at that time had advanced to such an extent that exfoliation of bone from

various parts of the body had taken place, especially from ulcers of the scalp, tibia, etc. The bones of the nose were coming away, accompanied by much of the nasal tissue, producing a hideous appearance and offensive in the extreme. The patient was a married woman, no children, fifty years of age. The past two years she was absolutely unable to help herself, confined to bed all the time, and of course a great sufferer. She was very fond of cats, and kept one or two about the bed much of the time during the last year of her life. About fifteen months ago the cat which slept most of the time in bed with her became sick, moped about the room, with swollen eyes and purulent discharge from the nose, sneezing, and soon became a horrid spectacle and finally died, greatly emaciated. While this unfortunate feline was pining away, the patient had adopted another bedfellow of the same species; in about two months this cat sickened and died precisely as the former, with symptoms corresponding to those of its affectionate mistress and its hideous predecessor. Another was then taken in bed to be caressed and to die in about the same length of time, and with the same symptoms. The husband of this poor woman saw by this time the fatal effects upon the gentle mousers, but not willing that his wife should be deprived of any comfort in his reach, procured another famous "rat catcher" from a negro in the immediate neighborhood, and brought it to the now sinking patient, who soon fondled it into perfect acquiescence, and, as the shadows began to lengthen, it too manifested the same symptoms of nasal catarrh first, then swollen head, purulent discharge, sore eyes, cough, sneezing, emaciation, etc., until on November 20th last, the long-suffering woman died. That night the cat lay upon the hearth in a sort of comatose state, and lingered until the next day; it expired while the funeral cortege was moving off with the decomposing remains of its late bedfellow. This was the fourth victim in less than thirteen months. In visiting regularly at this house my attention was called to the little animals, as one by one they succumbed to the dreadful malady. Observing the symptoms closely, I can vouch for the truth of this case as one where disease from the human subject was communicated to the lower animal. Dr. Chisholm says, in substance, that while it is a well-established fact that diseases of the lower animals are frequently communicated to the human race, the converse is not so well authenticated.

W. C. McDuffie, M.D.

Fayetteville, N. C.

THE TREATMENT OF PNEUMONIA.

To the Editor of The Medical Record.

Sir: Having noticed that the fatality attending pneumonia in some parts of our country has attracted the attention and comment of non-professional, as well as professional, journals, with your permission I will give your readers an outline of the treatment which I have long used with most satisfactory results.

At present I shall have nothing to say about theory, but if any gentleman shall condemn my practice because it may seem to conflict with any theory, I shall in a future paper answer him, perhaps.

In general, the treatment of pneumonitis is very simple indeed. The great desideratum is an equable, constant temperature of the atmosphere of the patient's room. He requires nothing less than a warm-air bath, or a hot-air bath, from the earliest period of his attack until the lung inflammation has been subdued, and the fever has in great measure subsided.

The condition of the patient's skin must determine what degree of heat the air of his room shall rest at. In general, somewhere about blood-heat will be found the proper mark, but the conditions desired are a gentle perspiration from the entire surface of the body, and a respiration as free from labor and pain as may be. The patient should lie upon a couch removed from the door that is opened to admit attendants, etc., in order that no cold air may reach his lungs, and no covering save a sheet should be allowed him. In all cases the air of the room must be kept of sufficient warmth to prevent any chilly sensations. Thus it will be seen that the patient is immersed in a lung and a skin bath, which must be continued until the inflammatory, and the consequent febrile, stages have passed. This may be a period of a few hours only, or it may continue two, three, or four days; but when applied early this treatment usually aborts the disease in a short time. Whatever the duration may be, when it becomes evident that the active stage is passed, the temperature of the room may be slowly and cautiously lessened, while additional covering is as gradually put upon the patient.

When the patient is first denuded of his clothing (which should always be done when he is placed in the warm room, as above directed), the attendant should sponge him all over frequently with tepid water, until he begins to perspire. Cool drinks may be allowable, but warm are better. Ice and cold water should be excluded from the sick-room entirely.

Such are the conditions under which the inflamed lungs may, as a rule, be expected to recover health spontaneously.

And permit me to say that a wide departure from these conditions, at the behest of a fashionable clamor for fresh air, has given pneumonitis much of its terror.

Now, then, for the drugs necessary: Of course, at as early a stage as possible a purgative suitable to the condition of the patient should be administered, and if necessary repeated until effective. At the same time I would prescribe thus:

℞. Pulv. ipecac,
Sulphate quinine.....āā. grs. xvj.
Podophyllin..... grs. ij.

Mix and divide into sixteen powders (or pills if condition of patient's stomach requires). One to be given every four hours.

Should there be nausea, or any evidence of biliousness, I should add to the foregoing formula: calomel, grs. ij.

I most earnestly wish to call attention especially to the conditions above outlined—the absolute necessity of excluding cold air from inflamed lungs—and hope that some of the Record's readers will test this matter for themselves and report results for the benefit of others. I can assure you that this is no new hobby upon which I am desirous of cantering into public notice, but a well-tried and, to me, a thoroughly proven improvement upon the ordinary mode of managing pneumonitis.

In hospital practice it will be easy to provide suitably heated wards, but in private practice it will often be found difficult to constantly and equably supply the proper degree of heat. To obviate this difficulty I have devised a portable room which answers the purpose. To any gentleman who may wish to have what little assistance I can give I will send plan of said room, and gladly reply to all inquiries which he may make.

Allen, La.

Wholesale Dissemination of Syphilis.—Professor Tarnowski, of St. Petersburg, says that a syphilitic woman who had come under his observation had succeeded in contaminating with syphilis no less than three hundred men within a period of ten months. This represents merely the primary transmission of the disease; it naturally takes no account of the syphilitic taint which would reach the offspring of the men who suffered. Thus from one source, that of an infected woman, an amount of syphilis was disseminated, and injury done to healthy persons, which it is scarcely possible to estimate.

New Instruments.

A NASAL DOUCHE CUP.

By LEONARD A. DESSAR, M.D.,

NEW YORK.

So much has been written regarding the danger of middle-ear catarrh from the use of nasal douches, as well as the inconvenience of applying them in the ordinary manner, that I have endeavored to construct an instrument which, to a great extent, obviates these disagreeable features.

It consists of a cup made of glass, the nozzle being made to fit into the nostril, and the fluid introduced into

the nose by inclining the head somewhat forward, the mouth being kept open. The illustration conveys a correct representation of the cup, which is about double the size of the cut.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 24 to March 2, 1889.

McKEE, JAMES C., Lieutenant-Colonel and Surgeon. By direction of the Secretary of War, granted leave of absence for two months. Par. 13, S. O. 44, A. G. O., Washington, February 24, 1889.

GREENLEAF, CHARLES R., Major and Surgeon. Will proceed from this city as early as practicable to Newport Barracks, Ky., to examine and report upon a proposed change in the location of the post hospital at the new barracks now in process of construction near that post; thence to Columbus Barracks, O., to examine and report upon the necessity for an addition to the hospital at that post. Par. 16, S. O. 43, A. G. O., Washington, February 20, 1889.

BYRNE, CHARLES B., Captain and Assistant Surgeon. Granted leave of absence for twenty-one days. S. O. 44, Headquarters Division of the Atlantic, Governor's Island, New York City, February 21, 1889.

OWEN, WILLIAM O., JR., Captain and Assistant Surgeon. By direction of the Secretary of War, relieved from duty at Fort Leavenworth, Kan., and will report in person to the commanding officer, Fort Gibson, Indian Territory, for duty at that post, relieving Captain C. N. B. Macauley, Assistant Surgeon, who, on being so relieved, will report in person to the commanding officer, Fort Leavenworth, Kan., for duty at that post. Par. 3, S. O. 48, A. G. O., February 27, 1889.

TO MAKE MILK DIGESTIBLE advise patients to sip rather than gulp it. The fluid will then have a chance to become intimately mixed with the saliva and not miss the first important digestive process. Nature teaches the babe to do this in the ordinary function of suckling, supplying the nutriment in small quantities for the purpose.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 2, 1889:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	6	2
Scarlet fever	359	43
Cerebro-spinal meningitis	3	2
Measles	305	19
Diphtheria	177	42
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

A COURAGEOUS WOMAN.—At Surugadai, in Tôkyô, lives Mr. Tanabe, a gentleman in easy circumstances. His mother, an inmate of the same house, has attained her sixtieth year, but, until quite lately, was a hale and hearty lady, much beloved for her virtues and esteemed for her accomplishments. The changes of these topsy-turvy times have not shaken her adherence to the faiths and fashions of ancient days. In her eyes the Japanese *samurai* still exists, though his name has been erased from the national ledger and his place usurped by inferiors. A few months ago, her wonted health began to fail. She was attacked by a disease formerly held fatal, and now known to be curable only by extreme measures. At the Hongo Hospital Dr. Sato told her that a severe surgical operation could alone save her life. Was it possible that a lady of her age should survive such a method of treatment? Dr. Sato said there was good hope, and after anxious consultation her family consented to follow his advice. The old lady at once became an inmate of the hospital. By the 24th ultimo, she had undergone the necessary preparation. Dr. Sato himself undertook the operation, in the presence of the chief surgeons of the Naval and War Departments and of the Imperial University. Two deep incisions in the bosom had to be made, and the assistants were about to administer chloroform. The old lady asked what was the nature of the medicine. Being told that its function was merely to deaden pain, she said that she had no need of such things. She had heard of anodyne drugs that send patients to sleep under the surgeon's knife. She preferred to remain awake. Among her friends of former days was a loyal soldier, by name Miyoshi. Fate willed that he should die by his own sword. He had disembowelled himself in her presence, and with a wide wound gaping in his bosom, had composed and written his death song. She had witnessed this thing with her own eyes. It was her notion of the example a *samurai* ought to set, and though a woman, she preferred to emulate such a spirit rather than to take refuge from pain in narcotics. With that she lay down, and bared her bosom to the knife. Dr. Sato proceeded with the operation. He made two incisions, about four inches each, in the form of a cross, under the left breast, and two smaller incisions above. From each wound a large abscess was removed, and twenty stitches were put in. During the whole process the old lady never made a movement or uttered a groan. Not until Dr. Sato asked whether she had suffered much pain, did she open her eyes and reply quietly that the cutting of live flesh is never without suffering. Her son, who was by her side throughout, would now have answered the various inquiries that had come by telegraph and messenger, but the old lady insisted on writing four letters herself to reassure her friends. Dr. Sato declared, as well he might, that he had never, in all his experience, encountered so much fortitude and power of endurance. The *Nichi Nichi Shimbun* tells the story as an evidence that the old *samurai* spirit survives in Japan.—*Japan Mail.*

THE ETIOLOGY OF CROUPOUS PNEUMONIA.[1]

BY GEORGE M. STERNBERG,

MAJOR AND SURGEON, UNITED STATES ARMY.

ACUTE pneumonia is now generally regarded by the leading clinical authorities and pathologists in this country and in Europe as a specific infectious disease. Green, in his article on "Inflammation of the Lungs," in Quain's "Dictionary of Medicine," says: "It is maintained by some observers that, like the specific fevers, it is due to a specific cause. Pneumonia, whilst differing from these fevers in not being contagious, resembles them in the typical character of its clinical phenomena, and to a less extent of its local lesion. The changes in the lung occurring in pneumonia cannot be induced by artificial injury of the organ, and it must therefore be admitted that there is something special in the inflammatory process."

This "something special" has been demonstrated by recent researches, and it is the object of the present paper to give a historical account of the development of our knowledge with reference to this specific infectious agent, and of the experimental evidence upon which the claim is founded that the micro-organism referred to bears an etiological relation to the disease in question.

Evidently, if pneumonia is a specific infectious disease, the micro-organism which causes it is widely distributed, and the development of an attack depends rather upon secondary predisposing and exciting causes than upon the accidental introduction of the specific agent.

It cannot be maintained that the disease, as a general rule, is transmitted from individual to individual, *i.e.*, by personal contagion. Clinical experience is entirely opposed to this view, although we have ample evidence that it may occur as an epidemic among individuals who are exposed to the same conditions of environment—as in jails, barracks, etc. Thus at Christiana, Sweden, an epidemic of pneumonia occurred in 1847 in the prison, during which sixty-nine of the prisoners were attacked. And again in 1866 and 1867, during a period of six months (December, 1866, to May, 1867), a similar epidemic was observed in the same prison—sixty-two cases. Other prison epidemics recorded are those at Frankfort in 1875 (seventy-five cases) and in 1876 (ninety-eight cases); at Maringen in 1875 (eighty-three cases) and in 1878 (fifty-eight cases); at the prison of d'Ansberg in 1880 (one hundred and sixty-one cases, with forty-six deaths, in a period of five months).

Again, we have numerous records of village epidemics and of epidemics confined to single houses. In outbreaks of this character, as in epidemics of typhoid fever, of cholera, and of yellow fever, there is a succession of cases occurring at different intervals, but it does not follow that these cases bear any direct relation to each other. On the contrary, everything indicates that, as in the diseases mentioned, in the presence of the infectious agent common predisposing causes relating to the environment, acting upon persons having various degrees of resisting power, induce attacks at various intervals; or, it may be that in the presence of the specific cause and predisposing influences an exciting cause, such as exposure to cold, alcoholic excess, etc., is the immediate factor in the development of an attack.

Without stopping to discuss further the facts relating to the epidemic prevalence of the disease under consideration, I call attention to the well-established fact that pneumonia prevails over a wide area of the inhabited surface of the earth, and that by far the larger number of cases occur independently of any recognized connection with previous cases, and often under circumstances in which such connection can be very positively excluded. And, on the other hand, the direct transmission of the disease by the sick to those most closely associated with them, as nurses, etc., if it occurs at all, is evidently a rare exception to the general rule.

We must then conclude, as stated at the outset, that if pneumonia is a specific infectious disease the micro-organism which causes it is widely distributed. As a matter of fact, the pathogenic micrococcus which, from the evidence now at hand, appears to be the specific etiological agent in acute pneumonia has been found in the buccal secretions of healthy individuals in various parts of the world—in America, in France, in Italy, and in Germany, and no doubt more extended researches will show that it is extremely common.

This statement may appear at the outset to make the view that the micrococcus in question is the cause of croupous pneumonia quite untenable. For, it may be asked, how is it that the individuals who have this micro-organism in their buccal secretions escape an attack of pneumonia? In the present state of our knowledge this question no longer presents any serious difficulties. We know, for example, that the pus-organisms—staphylococcus pyogenes aureus, albus, and citreus—are very frequently found in the buccal secretions, and on the surface of the body of healthy individuals, and that, although these micrococci are recognized as the cause of furuncles and of all sorts of acute abscesses, they only give rise to the formation of such abscesses under certain special conditions relating to the general health of the individual, or to a traumatism by which their introduction to vulnerable parts is effected. Again, the tetanus bacillus is a widely distributed micro-organism which has been found in the earth, and especially in rich loam, in various parts of the globe. But the hands of farmers and gardeners are constantly soiled with such earth, without their contracting tetanus. In this instance it has long been recognized that a traumatism is an essential factor in the chain of events which leads to the development of tetanus, and now we believe, on satisfactory experimental evidence, that it is not the traumatism *per se*, or the injury to nerves, or exposure to cold, which in certain cases gives rise to this infectious malady, but that the result depends upon the introduction of a specific infectious agent at the time the wound was received, or subsequently—the tetanus bacillus of Nicolaier.

In the case of the tubercle bacillus, also, it is extremely probable, in the light of our present knowledge, that this bacillus, in a living condition, not infrequently finds a lodgement in the mouth, upon the Schneiderian mucous membrane, or in the larger bronchial tubes of most individuals who live in populous communities. Here, also, the infectious agent is only one factor, although an essential one, in the production of the infectious disease. It must be introduced to the vulnerable location, and must find a favorable nidus in the tissues invaded. We have good

[1] Read at the meeting of the Medical Society of the State of New York, at Albany, N. Y., February 6, 1889.

reason to believe that in this, as well as in other infectious diseases, there are wide differences, inherited or acquired, in the susceptibility of the tissues to invasion when the infectious agent has been introduced to a favorable location.

In a paper read before the Pathological Society of Philadelphia, in April, 1885, in discussing the relation of my *Micrococcus Pasteuri* to croupous pneumonia, I say: "It seems extremely probable that this micrococcus is concerned in the etiology of croupous pneumonia, and that the infectious nature of this disease is due to its presence in the fibrinous exudate into the pulmonary alveoli.

"But this cannot be considered as definitely established by the experiments which have thus far been made upon the lower animals. The constant[1] presence of this micrococcus in the buccal secretions of healthy persons indicates that some other factor is required for the development of an attack of pneumonia; and it seems probable that this other factor acts by reducing the vital resisting power of the pulmonary tissues, and thus making them vulnerable to the attacks of the microbe. This supposition enables us to account for the development of the numerous cases of pneumonia which cannot be traced to infection from without. The germ being always present, auto-infection is liable to occur when, from alcoholism, sewer-gas poisoning, crowd poisoning, or any other depressing agency, the vitality of the tissues is reduced below the resisting point. We may suppose, also, that a reflex vasomotor paralysis, affecting a single lobe of the lung, for example, and induced by exposure to cold, may so reduce the resisting power of the pulmonary tissue as to permit this micrococcus to produce its characteristic effects.

"Again, we may suppose that a person, whose vital resisting power is reduced by any of the causes mentioned, may be attacked by pneumonia from external infection with material containing a pathogenic variety of this micrococcus having a potency, permanent or acquired, greater than that possessed by the same organism in normal buccal secretions."

This is the theory by which I have attempted to explain the etiological rôle of this micrococcus in croupous pneumonia. Let us now consider the principal facts which have led to a belief in its causal relation to this disease.

Friedländer,[2] in 1882, observed, in eight fatal cases of pneumonia in which he made autopsies, micro-organisms having an oval form in the exudate into the pulmonary alveoli; they were in pairs or in short chains. Without affirming that this micro-organism is the cause of pneumonia, Friedländer seems to have considered it extremely probable that it bore an etiological relation to the disease.

During the same year Leyden and Gunther announced at a meeting of the Medical Society of Berlin (November 20, 1882) that they had found the same micrococcus in the fibrinous exudate of pneumonia, obtained through the thoracic walls by means of a Pravaz syringe. At the same time Gunther stated that the elliptical cocci, in specimens stained with gentian violet, were surrounded with a colorless capsule.

The following year Matruy[3] published his observations. In sixteen cases he had found an elongated coccus in the fibrinous exudate of pneumonia, and always having a very transparent capsule. He had also encountered the same micro-organisms in the sputa of patients with other diseases, but not so abundantly as in pneumonia.

On November 19, 1883, Friedländer[4] communicated to the Medical Society of Berlin the results of his culture and inoculation experiments. His "pneumococcus" was characterized by the presence of a capsule which, as he says, "always takes the form of the micro-organism; if this is round the capsule is round; if it is elliptical the capsule is an ellipse." This capsule, however, was only found in preparations made from the blood of an inoculated animal, or from the fibrinous exudate into the alveoli; in cultures it was no longer seen. The cultures in flesh-peptone gelatine presented a nail-shaped growth which was believed to be characteristic. Growth was rapid in a variety of culture-media at the ordinary room-temperature (65° to 75° F.), and in a gelatine culture-medium no liquefaction occurred.

The following results were obtained by Friedländer in his inoculation experiments: In one series of experiments the "pneumococci," mixed with distilled water, were injected through the thoracic walls into the lungs. Nine rabbits inoculated in this way gave an entirely negative result. Six out of eleven guinea-pigs are said to have succumbed and to have presented the lesions of pneumonia. All of the mice injected died within twenty four hours, and at the autopsy the lungs were found to be congested and to present foci of red hepatization. In a second series of experiments upon mice they were made to inhale a spray containing the pneumococci in suspension. Several of these animals died, and are said to have presented a typical pneumonia. The "pneumococcus," surrounded by its characteristic capsule, was found in the lungs, the spleen, the blood, and the liquid contained in the pleural cavity.

Upon this evidence Friedländer's "pneumococcus," which is now usually described as a bacillus, was very generally accepted as the specific cause of fibrinous pneumonia, and cultures were distributed throughout the laboratories of Europe bearing the label, "Pneumococcus of Friedländer." For some time after the publication of Friedländer's paper all observations made with reference to the presence of oval cocci or of incapsulated cocci in the fibrinous exudate of pneumonia were supposed to confirm his discovery. But now we know that there is another oval coccus which is far more frequently present in the exudate of acute pneumonia, which also presents the appearance of being surrounded by a transparent capsule—less pronounced, however, than that of Friedländer's bacillus—but which is entirely distinct from that of Friedländer, and is probably the true pneumococcus. I shall give the distinctive characters of this micro-organism later.

At the same time that Friedländer was pursuing his researches in Berlin, Talamon, a French physician, was engaged in similar researches in the laboratory of the Hôtel-Dieu. His results were communicated to the Anatomical Society of Paris on November 30, 1883, a few days after Friedländer's communication to the Medical Society of Berlin (Germain Sée).

"Talamon did not describe his microbe as having a capsule; according to him the pneumonia-coccus is characterized by its form. When seen in the fibrinous exudate the microbe has an elliptical form, like a grain of wheat. Cultivated in a liquid medium—an alkaline solution of extract of beef—it is elongated and attenuated, and presents the appearance of a grain of barley. On account of this appearance Talamon has proposed to call it the *lanceolate coccus*. This organism is encountered in the pneumonic exudate obtained after death, or drawn during life by means of a Pravaz syringe from the hepatized portions of the lung. Once only, out of twenty-five cases, it was found in the blood of a patient at the moment of death."

Talamon's inoculation experiments in dogs and guinea-pigs gave a negative result, but out of twenty rabbits injected through the walls of the thorax into the lungs eight showed the characteristic lesions of fibrinous pneumonia. Professor Sée says, with reference to the evidence in the case of these rabbits as compared with that obtained by Friedländer in his mice: "The rather brief description of the lesions obtained by Friedländer in the mice inoculated by him leaves some doubt in the mind;

[1] I should have said frequent instead of "constant presence."
[2] Die Schizomyceten bei der acuten fibrinösen Pneumonie, Virchow's Arch., 1882, Bd. lxxxvii.
[3] Ueber Pneumonie-Kokken, Wiener med. Presse, June, 1883.
[4] Die Mikrokken der Pneumonie, Fortschritt der Medicin, Bd. i., 1883.

for the presence of foci (noyaux) of induration in congested lungs is not sufficient to characterize fibrinous pneumonia. But the lungs of the rabbits presented by Talamon to the Anatomical Society in support of his communication leave no room for discussion. As he observed, it was not at all a question of foci of congestion, or of broncho-pneumonia, such as one observes habitually in rabbits which die of septicæmia, but a veritable lobar fibrinous pneumonia with pleurisy and pericarditis of the same nature. The naked-eye examination, as well as the microscope, showed no difference in the lesions produced in the rabbit and the pneumonia of man."[1]

On another page Professor Sée says: "Afanassiew repeated in the laboratory of Professor Cornil the experiments of Friedländer and of Talamon; by the culture in peptonized gelatine of the pneumonic exudate taken from the cadaver, he obtained two species of organisms, round micrococci of large and small dimensions, and oval cocci which corresponded to the microbes described by the two authors" (Friedländer and Talamon) "whose researches we have just reviewed." This quotation indicates that Professor Sée did not question the identity of the oval or "lanceolate" coccus found by Talamon in pneumonic exudate, and which in his experiments produced typical pneumonia in rabbits, and the so called "pneumococcus" of Friedländer, which, according to his account, gave a negative result when injected into rabbits, but caused pneumonia in mice when injected directly into the lungs. Professor Sée was not alone in making this inference, which has turned out to be a mistaken one. The identity of the oval cocci, which had now been seen in the pulmonary exudate by numerous observers, with the micro-organism which Friedländer had isolated and cultivated from material obtained post mortem from hepatized lungs, was generally admitted; and all of the observations relating to the presence of oval cocci, having a more or less distinct capsule, in the exudate of fibrinous pneumonia, were supposed to give support to the alleged discovery of Friedländer. Now we know that the oval coccus most frequently found in such material is not that of Friedländer, but that it is identical with a coccus first observed by the writer in September, 1880, in the blood of rabbits injected with his own saliva and subsequently (1885) named by me *micrococcus Pasteuri.*

This was, without doubt, the coccus which produced pneumonia in Talamon's experiments upon rabbits; and we must give him the credit of having first experimentally demonstrated the fact that fibrinous pneumonia may be induced by the introduction of this micro-organism into the parenchyma of the lung in these animals.

Salvioli, whose experiments were also made in 1884, had a uniformly fatal result from the injection of pneumonic sputum into rabbits (4). He also observed the oval coccus in the material injected, and in the blood of the animals which succumbed to his injections, but did not recognize the identity of this coccus with that which my own experiments and those of Pasteur, Vulpian, and others had shown to be present in normal human saliva, and to induce a fatal form of septicæmia in rabbits. On the other hand, he also appears to have taken it for granted that the oval micrococcus encountered by him, and which, under certain circumstances, was surrounded by a transparent capsule, was the "pneumococcus" of Friedländer. Klein[2] appears to have made the same mistaken inference. This is shown by the following quotation from his paper published in 1885:

"In seeking to ascertain what might be the relation between the so-called pneumococci and croupous pneumonia, I have made extensive examination of the lungs and blood of persons dead of the disease, and also of the sputum of living patients at various stages of their illness. . . . In some of the air-vesicles, though few and far between, there were present undoubtedly the capsulated cocci spoken of by Friedländer and others as pneumococci. . . . As regards the living patients, if we examine typical sputum of croupous pneumonia, we find, besides numerous red blood-disks and white blood-corpuscles, also a few epithelial cells, and in the general gelatinous matrix numbers of micro-organisms, chiefly belonging to the species micrococci. . . .

"These are, as far as size and arrangement go, of two principal types: (*a*) Oval micrococci about 0.001 mm. in length, occurring isolated, but more commonly as dumb-bells and slightly curved chains of four, six, and even eight elements. . . . But in all these micrococci the elements are distinctly surrounded by a hyaline zone which, in stained preparations, can be made out as an unstained halo; though in some stained specimens it assumes a tint that is fainter than that of the micrococcus itself; this corresponds to the capsule of Friedländer, and for this reason he called them capsule micrococci."

In a foot note to the paper from which I have quoted, Klein says:

"While this paper is passing through the press I receive from Dr. Sternberg, of Baltimore, a paper in which he conclusively proves that the micrococci of human saliva, which produce in some instances septicæmia on inoculation into rabbits, are identical with the pneumococci of Friedländer, Salvioli, and others."

My own experiments with pneumonic sputum were made in January, 1885, and led me to the identification of the oval coccus found in this material with the coccus found in my own saliva (by inoculations in rabbits), in September, 1880, and subsequently studied by me in an extended series of experiments made during the following years, 1880–84.[1]

But, at the same time, I fell into the error of inference, previously made by Professor Sée, by Salvioli, and others, and assumed that the "pneumococcus" which Friedländer had obtained from the same source was the same, although I found it difficult to reconcile the experimental data, inasmuch as he had obtained uniformly negative results in his inoculations into rabbits. To explain this discrepancy I suggested that Friedländer's pneumococcus was probably a variety having a different degree of pathogenic power.

This supposition seemed to find support in the fact, which I had previously observed, that my micrococcus Pasteuri became attenuated, as to its pathogenic power, when the cultures were kept for some time; and that there seemed, from the experimental evidence before me, to be different pathogenic varieties in the buccal secretions of different individuals. At this time I had not seen a culture of Friedländer's bacillus. Later in the autumn of 1885, when I made its acquaintance in Dr. Koch's laboratory, I recognized my mistake and hastened to correct the error.[2]

For a detailed account of my experiments with pneumonic exudate, I must refer to my paper published in the "Transactions of the Pathological Society of Philadelphia" (vol. xii.), and in the *American Journal of the Medical Sciences* (July, 1885).

With reference to my conclusion that the oval coccus of Talamon and of Salvioli was identical with my micrococcus Pasteuri, I may say that this conclusion has been

sustained by the subsequent investigations of Fränkel, Weichselbaum, Bordoni-Uffreduzzi, Netter, Gamaléia, and others.

Fränkel's first paper relating to the presence of this micro-organism in pneumonic exudate was published in 1885.[1]

Having ascertained that his own saliva contained this oval micrococcus, he was induced to make an extended and interesting series of experiments which led him to the conclusion that this micro-organism is far more constantly present in the exudate of fibrinous pneumonia than is the so-called "pneumococcus" of Friedländer. He says:

"Finally, as regards the relative frequency of the two hitherto investigated micro-organisms in cases of pneumonia, no positive statement can yet be made. Nevertheless, I am inclined to regard the lancet-shaped pneumococcus, which is identical with the microbe of sputum septicæmia, as the more frequent, and the usual infectious agent of pneumonia, on the ground that this organism is so much more frequently found in the sputum of pneumonic patients than in that of healthy individuals. This conclusion is further supported by the fact that it has not hitherto been possible to isolate, directly from the rusty sputum Friedländer's bacillus."[2]

The extended researches of Weichselbaum,[3] published in 1886, give strong support to the view that this coccus is the usual infectious agent in croupous pneumonia. He examined, in all, the exudate in 129 cases of pneumonia.

In 94 of these cases the micrococcus in question, called by Weichselbaum "diplococcus pneumoniæ," was obtained (54 times in cultures); in 21 cases he obtained a streptococcus, and in 9 only was the bacillus of Friedländer encountered.

Wolf,[4] whose studies were made in Weichselbaum's laboratory, reported the result of his researches in 1887. He found the "diplococcus pneumoniæ" in 66 out of 70 cases of croupous pneumonia examined, and the "pneumococcus of Friedländer" in 3 cases.

Netter,[5] whose paper was published in November, 1887, found M. Pasteuri in seventy-five per cent. of his cases of pneumonia, and in the sputum of convalescents from this disease its presence was verified in sixty per cent. of the cases by inoculation experiments in rabbits. He makes the interesting observation that the sputum of recent convalescents is less virulent for rabbits than that collected at a later period.

Gamaléia, who has recently published in the "Annales" of the Pasteur Institute an important paper upon the etiology of fibrinous pneumonia, verified the presence of M. Pasteuri in twelve fatal cases, in which he collected material post mortem. He states that in a series of 40 consecutive cases Dr. Goldenberg, whose experiments were made in his laboratory, found this micrococcus in every case by inoculation experiments in rabbits or in mice. According to Gamaléia, inoculations in mice are more reliable than those made in rabbits, as the mouse is the more susceptible animal. He says: "The author, Weichselbaum, who has made the most extended research upon the etiology of pneumonia, used in his researches the method of cultivation upon gelatine. We must adopt the opinion of Baumgarten, who does not accord any decided value to the negative results of Weichselbaum with reference to the constant presence of streptococcus Pasteuri. Netter, who adopted the method of inoculating the pneumonic sputum into rabbits, and who only found the microbe of Pasteur in seventy-five per cent. of his cases, was wrong, in our opinion, in making use of an animal which is too resistant to determine the presence of small quantities of virus. This opinion is confirmed by the fact that Netter rendered some rabbits refractory by his inoculations with material in which he had not found the specific microbe."

"*En résumé*, taking our stand upon the positive results which we have always obtained, as well as upon the superiority of the method of research (inoculations in mice), which we have adopted, we believe ourselves authorized to conclude that fibrinous pneumonia is always dependent upon the microbe of Pasteur."[1]

Fränkel, Weichselbaum, and other recent authors, while maintaining that micrococcus Pasteuri is the most frequent etiological agent in the production of pneumonia, have been disposed to admit that in a certain proportion of the cases the bacillus of Friedländer, and possibly other micro-organisms, may bear the same relation to the pneumonic process. Gamaléia, on the other hand, believes that the bacillus of Friedländer is a simple saprophyte, the occasional presence of which in pneumonic exudate is without etiological import. He remarks as follows:

"We may be brief as regards the second objection made against the etiological unity of fibrinous pneumonia, viz., with reference to the etiological rights of the microbe of Friedländer. This microbe is found in normal saliva, it is a true saprophyte, and may at times invade the diseased or dead lung. Weichselbaum only found it in seven per cent. of his cases, and almost always associated with other microbes, for he only encountered it pure in three cases. As to the researches of the authors who preceded Fränkel, it is sure that the microbe which they often found in sections of diseased lungs, and which they called the microbe of Friedländer, was in fact the microbe of Pasteur, since it was colored by the method of Gram, which decolorizes the bacillus of Friedländer. Many of the positive results, then, which have been reported relative to the last-mentioned micro-organism, ought to be put to the account of the other."

This opinion the present writer has entertained since his researches made in 1885.

The experimental evidence offered by Gamaléia in favor of the etiological rôle of this micrococcus is most important.

It will be remembered that Talamon produced typical pneumonia in eight rabbits, in 1883, by inoculating them through the thoracic walls with pneumonic exudate. Gamaléia says:

"The number of my rabbits in which pneumonia was induced is about two hundred."

The writer found in his experiments, made in 1881, that in making a series of inoculations in rabbits the virus increased in virulence; and that, on the other hand, the micrococcus lost its virulence when the cultures were kept for some time. This fact has been verified by the subsequent researches of Fränkel and of Gamaléia. The last-named author has shown that to induce pneumonia in very susceptible animals, like the rabbit, an attenuated variety of the microbe should be injected, for the most virulent cultures quickly cause death by septicæmia. As he expresses it: "Animals which are too susceptible, like the rabbit and the mouse, do not have pneumonia, because they do not offer a local reaction; the virus is generalized in their bodies, and they die of an acute septicæmia."

On the other hand, Gamaléia has shown that "animals which are but little susceptible to the pneumonic virus offer a local resistance which gives rise to very pronounced reactionary phenomena (extended fibrino-granular œdema), and consequently they present, as a result of intra-pulmonary infection, a typical fibrinous pneumonia. Such animals are the dog and the sheep."

In his experiments upon these animals Gamaléia obtained the following results:

The sheep was found to survive subcutaneous inoculations, unless very large doses (5 c.c.) of the most potent

virus were administered. But intra-pulmonary inoculation was always followed by typical fibrinous pneumonia, which in the majority of cases proved fatal.

The microbe was rarely found in the blood, and successive inoculations from one sheep to another were not successful. Death occurred, after an intra-pulmonary inoculation, on the third, fourth, or fifth day. The pneumonia produced was lobar, and was attended with an extensive fibrinous exudation in which the coccus was found in great abundance. In all, fifty sheep were experimented upon.

The writer found in his experiments, made in 1881, that the dog resists inoculations with this coccus. Gamaléia also obtained negative results when moderate doses were injected beneath the skin, but states that "intra-thoracic infection always causes a frank, fibrinous pneumonia which is rarely fatal; recovery usually occurs in from ten to fifteen days, after the animal has passed through all the stages of red and gray hepatization which characterizes this affection in man." Twelve dogs were experimented upon.

This micrococcus, then, which in very susceptible animals (mouse, rabbit) invades the blood and quickly causes death by septicæmia, when injected through the thoracic walls in less susceptible animals (dog, sheep), or in an attenuated form in the rabbit, gives rise to the local lesions which characterize fibrinous pneumonia.

Man comes in the category of slightly susceptible animals, as is shown by the comparatively small mortality from pneumonia, and the fact that the micrococcus found in the exudate into the pulmonary alveoli does not invade the blood, unless in rare instances. We may therefore agree with Gamaléia in the following statement:

"It is clear that the results obtained in the dog and the sheep, animals which have but a slight susceptibility, are most applicable to human pathology."

In my paper read before the Pathological Society of Philadelphia in April, 1885, from which I have already quoted, I say: "It seems extremely probable that this micrococcus is concerned in the etiology of croupous pneumonia. . . . But this cannot be considered as definitely established by the experiments which have thus far been made upon the lower animals."

The experiments of Gamaléia go far toward settling this question in a definite manner, and, considered in connection with those of Talamon and Salvioli, and the extended researches of Fränkel, Weichselbaum, and Netter, leave but little doubt that this is the true infectious agent in acute lobar pneumonia.

(To be Continued.)

PERIODICAL NEURALGIA OF THE CORNEA.—Dr. Granclément, of Lyons, has described an affection which, he says, is rather frequent, consisting in a sort of periodical and ill-defined neuralgia of the cornea, following a very slight traumatism of this membrane. The traumatism consists, more frequently, in a simple grazing by the leaf of a shrub, the finger of a little child, or any other soft body which cannot do much hurt. To this condition he has applied the term traumatic keratalgia. Soon after the accident, although the cornea presents no excoriation, the patient suffers a good deal and periodically from neuralgic phenomena which are reproduced irregularly for some years, like rheumatoid pains. One can only attribute these accidents to a slight neuritis of one or more of the ciliary nervous filaments of the cornea which are found in the sphere of action of this slight traumatism. If the stronger traumatisms of the cornea, such as those resulting from the incrustation of a splinter of iron, or any other metal, do not leave behind them similar neuralgias, it is because the nervous filaments touched had been destroyed, and not simply bruised. The only remedy which appears to relieve these patients is the employment of cocaine:—*Paris Correspondence of the Journal of the American Medical Association.*

PYELITIS AND AN ACUTE SUPPURATIVE NEPHRITIS CAUSED BY COMPRESSION OF THE URETER FROM A CICATRICIAL MASS, THE RESULT OF A PELVIC ABSCESS.

BY LEROY BROUN, M.D.,

NASHVILLE, TENN.

DURING my service as house-surgeon of the New York Cancer Hospital there came under my care a case as interesting as it was puzzling. Through the courtesy of Dr. James B. Hunter the particulars are given below:

The woman, a German by birth, had been in this country six years; she was single, and aged twenty-nine. She was of good habits, robust appearance, and, as was thought by all, to be of a hysterical nature. Five years ago she entered one of the general hospitals of the city for some minor complaint, attended by hysterical retention of urine.

While there she was catheterized frequently, and left the institution with a case of vesical irritation.

Finding, in time, no relief from her constant and painful micturition, she applied for admission at Bellevue Hospital, when she remained only a short while, leaving at her own request. We next hear from her in the spring of 1885, when, for the first time, she came under the notice of Dr. Hunter—at which time she complained of severe dysmenorrhœa, constant severe pain in the left groin, sacral pains, and frequent and painful micturition.

She was sent to the Woman's Hospital, and while there the examination of urine was negative. Not improving under treatment, an oöphorectomy was proposed, which she gladly accepted.

The relief brought about by the operation was only temporary, for in the fall of the same year she applied at the Polyclinic for relief from the same symptoms, excepting the dysmenorrhœa, which was gradually ceasing; she also complained of frequent attacks of severe congestive headache. Local examination showed sensitiveness in anterior cul-de-sac, and at the site of both pedicles—especially the right; all else was negative. During the following year a sanious discharge continued, at irregular intervals, attended by pain; though the headaches increased, and with them the local pain and sensitiveness.

She continued in this wretched condition until the summer of 1886, when she had an attack of pelvic inflammation caused by the passing of a sound. This resulted in the formation of a pelvic abscess to the right of the uterus, which, discharging into the vagina, rapidly healed and left a permanent induration the size of an English walnut.

During the time from her first application to the Polyclinic, up to 1888, she was under constant treatment, including almost every known method of relief, yet none afforded the desired improvement.

From her intractable headaches, pelvic and groin pains, she was, in part, the subject of a paper, "Persistent Pain after Laparotomy," by Dr. Hunter; also, "Cerebral Hyperæmia after Removal of Uterine Appendages," and "Is Disease of the Ovaries and Tubes as Frequent as Represented?" both by Dr. Coe.

Returning, as she often did, to Dr. Coe, he always found her condition locally the same. She frequently insisted on another abdominal section, but was dissuaded from it both by Dr. Hunter and himself. Finally, declaring that she would rather die than live as she was, and malignant disease of the intestines being suspected, she was sent to the Cancer Hospital to see what could be done.

Upon entering the hospital her physical condition was excellent, yet with a facial expression of nervous anxiety. The local conditions were as above described, with considerable tenderness over the mass on the right side. Frequent examination of the urine was always negative. The abdomen being opened by Dr. Hunter, it was found impossible to remove the mass, even by strong force, and, a few recent adhesions being broken up, the wound was

closed. She made a rapid recovery, and during the two weeks following showed no rise of temperature whatever.

Upon the fourteenth day she complained of slight pain over the right groin, which toward the afternoon increased greatly. At 8 P.M. the patient developed a severe chill, with a temperature of 103° F., and complained of severe pain over right side. Local examination showed exaggerated tenderness over the old localities, which was much so over the indurated mass. For the following twenty-four hours the temperature ranged between 103° and 104° F., with successive chills; pulse full. This high range with repeated chills continuing for the following day, the abdomen was reopened and careful search made for the seat of trouble, but to no effect. After repeated washing out with warm water a drainage tube was introduced, and wound closed. The tube was washed out every six hours. Upon the third washing about one ounce of pus was obtained; the washing was then continued every three hours.

For the succeeding six days the condition of the patient varied much. The temperature was that of one thoroughly septic, yet her pulse held out well. The washings were continued as above, the adhesions around the tube being broken up on two occasions under chloroform. For the last two days she rapidly grew worse, and died eight days after the occurrence of the first rise of temperature.

During this period the urine was daily examined and measured. The amount was not sufficient to excite any interest, and it contained no albumen or pus until four days before the termination. Toward the close the urine was loaded with pus and albumen, but no casts.

The post-mortem, conducted by Dr. Coe, showed the following: The spleen was enlarged and soft, and the liver congested. The intestines were matted together by organized lymph, general intense peritonitis existing everywhere. The cavity contained about thirty ounces of purulent fluid. The left kidney was markedly congested and ureter normal. The right was enlarged at the expense of the pelvis, which was much dilated and contained a few drops of pus; the pelvic mucosa was considerably thickened and intensely congested. On section of the organ the entire glandular portion was softened, and presented a yellowish appearance; upon close inspection streaks and foci of pus were visible. The right ureter was dilated to the size of the little finger and contained pus, while its walls were markedly thickened, as from an old inflammation.

The uterus was drawn backward and anchored to the right of the sacrum by a firm, fibrous mass. This organ was so firmly attached that it was impossible, through the exertion of considerable force, to detach it. The mass, the result of the old inflammation and abscess, extended upward along the right psoas muscle and compressed, but did not entirely occlude, the right ureter, which passed through it. On section this had a fibrous nature, and had, in its centre, a softened area with a few drops of pus. On the left side there was no trouble. The bladder was slightly congested at its base; the entrance of the right urethra was normal.

To sum up the above history and autopsy in a few words, we find that: 1. She had an attack of cystitis, probably of mild form, which subsided to one of slight vesical congestion. 2. She had severe headaches and other symptoms, all of which were referable to the pelvis, even before the pelvic inflammation and formation of adhesions, and all of which resisted the most approved treatment. 3. She had a dilated ureter and pelvis of long standing, as evinced in their thickened walls. This culminated in pyelitis with an acute interstitial suppurative nephritis; none of which was recognized during life.

The case presents points of unusual interest: First, the compression of the ureter by the fibrous mass, and, lastly, the failure to diagnose the glandular lesion. The last is of special interest to me, since it presents the question: Can the symptoms of slight inflammations of the pelvis and ureter be always recognized in those under treatment for diseases of the reproductive organs?

Given a pyelitis with suppurative nephritis, the constitutional symptoms, with the examination of the urine, are two great points, suggesting, as they do, closer examination of the lumbar region and previous history. But given a subacute inflammation of the pelvis and ureter in a woman under treatment—say, for a displaced uterus or ovarian trouble—do we not often overlook it?

The kidneys, pelvis, and ureter are under the control of the sympathetic nervous system. Branches from this plexus are directly connected with the ovarian sympathetic plexus. The uterus and its appendages are supplied by the sympathetic system, together with the third and fourth sacral nerves.

The sympathetic nerves, while capable of sensibility, are much less so than those of spinal origin.

These two sets of supply to the uterus and its annexa are intimately connected. Then is it not possible, and is it not the case, that the pain felt by a patient in a disturbance of the normal condition of the kidney, pelvic mucosa, and ureter, is referred chiefly by her to the pelvis, and to the course of the trigeminal nerve, which is intimately connected with the entire sympathetic system through its ganglia?

If this is true, I well see how she might overlook entirely her supposed minor trouble, and mislead the questioner, who, not finding grounds for her complaint, places her in the category of a hysterical woman.

There are two classes of cases somewhat parallel to this reflex neurosis—the one in man—where we often have, as the only symptom during the passage of a small renal calculus, that of pain in the corresponding testicle with drawing up of the same. Again, in old lacerations of the cervix, when any symptoms arise from it they are chiefly reflex, and prominent among them is the severe trigeminal neuralgia.

These few thoughts have not been suggested in order to explain the symptoms of the above case, the formation of the abscess and cicatricial mass, for certainly these strong adhesions attached to the fundus of the uterus were sufficient to occasion all of her sufferings, but seeking for their explanation before this period is the object of these lines.

The immediate cause of death in this case was evidently septic peritonitis, which had its origin in a sloughing area in the cul-de-sac, set up by the constant movement and pressure of the tube for such a time.

High and Cedar Streets, February 24th.

One Thousand Operations for Hæmorrhoids by the Method of Ligation.—Dr. J. M. Matthews, of Louisville, Ky., states (*The Journal of the American Medical Association*) that he has operated about one thousand times for hæmorrhoids by the ligature. He has never had to operate the second time upon the same patient for the affection. He has never had an unnatural contraction around the anus as the result of the operation, nor had ulceration or stricture to result. He has had one case of tetanus, which he believes to have been superinduced by a debauch, the patient having been drunk for several days before the operation. The tumors protruded, strangulated, and mortified, hence the operation. The patient recovered from the tetanus under bromide treatment. He has had one case of secondary hemorrhage occurring on the third day. The rectum was plugged and the bleeding stopped. Also one dangerous case of hemorrhage, which occurred one hour after operation was done, in consequence of the slipping of the ligature, the pile having been cut off. The patient was pulseless and cold when seen, but the artery was quickly secured and tied, and he made a good recovery. Dr. Matthews has never had a single death result from the operation, and but few untoward symptoms.

THE CAUSES OF RUPTURE OF CEREBRAL AND AORTIC ANEURISMS DURING SLEEP.

[By R. VAN SANTVOORD, M.D.,
NEW YORK.

In the *American Journal of the Medical Sciences* for March, 1889, the following passage occurs in a suggestive article by Dr. H. M. Biggs on "Aortic Aneurisms." "Contrary to what would *à priori* be supposed, death occurred in but few instances during severe muscular exercise. As a rule, there was no apparent immediate cause for the rupture, as it occurred during sleep, or at times when there was no unusual muscular exertion. This was also true of the two cases of rupture of the aorta; one occurred when the patient was lying in bed, and the second while the patient was returning home from work. This is rather a remarkable fact, and does not tend to confirm the usual opinion, that severe strains have so large an influence as has been ascribed to them in the production of the dilatation and rupture of the aorta."

A pathological fact similar to this, viz., the frequent rupture of miliary cerebral aneurisms during sleep, has for a long time been a puzzle to the writer. Reflection on the above-cited paragraph has suggested the following explanation of the phenomena:

During an active physical effort (*i.e.*, straining), the fact of a very great increase of arterial tension can readily be demonstrated by the sphygmograph. The factors which give rise to this increase are: 1. The increased peripheral resistance caused by the obstructed return of the blood to the thoracic and abdominal vessels, and the actual compression of peripheral vessels, especially the capillaries and veins, by the contracting muscles. 2. The increased friction arising from the increased rapidity of the blood-current, resulting from the increased rapidity of cardiac action. As soon as the effort ceases the blood pours with facility into the relaxed abdominal and thoracic vessels, the peripheral arteries relax, and the arterial tension falls rapidly. Such, at least, seems to be a fair interpretation of the sphygmograms that the writer has taken on himself during and after effort. During effort the glottis is closed, the thoracic and abdominal muscles contract, and the intra-thoracic and intra-abdominal pressure is greatly increased. This increased extra-vascular pressure must be more or less efficacious in offsetting the increased intra-vascular pressure during effort, as far as the abdominal and thoracic vessels are concerned. This seems to the writer a plausible reason why thoracic aneurisms do not rupture as frequently as might *à priori* be expected during severe muscular exercise. But why should they rupture during sleep or physical quiet? To this question the following answer is suggested. It is quite conceivable that the strain on the aorta might be greater when the arterial tension is increased by increased cardiac action without the safeguard of the increase of extra-vascular pressure, such as occurs during deliberate muscular effort. Such increase may be caused by shock or emotion. How great an effect this latter may have is strongly illustrated by a case of rupture of the aortic valves, recorded by Da Costa in his Toner Lectures. A young and previously remarkably healthy girl witnessed the shooting of a soldier who entered her residence, during the late war. She was greatly terrified, became from that moment very short of breath, and died shortly afterward with all the signs and symptoms of aortic regurgitation.

During sleep, when the inhibiting influences of the mind are inactive, a bad dream or a sudden noise will often give rise to excited cardiac action. The same effect will be produced by a sudden physical shock when awake, such as stumbling on an uneven pavement. Such occurrences, by reason of their commonness, are not apt to be remembered. Yet it is quite conceivable that an instantaneous increase of pressure caused by a few rapid and powerful cardiac contractions, due to the slamming of a shutter during sleep, might rupture an aneurism which, when guarded by the increased extra-vascular pressure incident to muscular exertion, could have borne exactly the same increase of intra-vascular pressure with impunity.

It is obvious that this explanation applies also to cases of cardiac rupture occurring during sleep or without physical exertion.

With regard to the common occurrence of cerebral hemorrhage during sleep, the following explanation is offered.

During effort the return of the blood from the head is impeded. The blood, dammed back in the cerebral veins and capillaries, distends them. This distention causes in the cerebral cavity an increased extra-arterial pressure which must have an effect in offsetting the increased intra-arterial pressure. Here again, as in the case of aortic aneurism, we might *à priori* expect the most danger from causes which give rise to increased intra-arterial pressure without any increase of extra-arterial support. Here again, slight shock from some internal or external source, not being opposed in its action on the heart by the inhibition of the fully awakened intellect, may cause damage which, at first sight, might seem disproportionately great. If these explanations are correct it follows, that shock and emotional disturbances are more potent factors in causing dangerous increase of intra-vascular pressure in the thoracic and cerebral vessels than physical strain. It would be of great interest to study individual cases as they present themselves to test the validity of these conclusions.

106 WEST 122D STREET.

A CASE OF MALIGNANT ENDOCARDITIS; INFECTION APPARENTLY FROM URETHRITIS.[1]

By JOHN S. ELY, M.D.,
NEW YORK.

Clinical History.—J. D——, male, aged twenty-eight, United States, waiter, single, walked into Roosevelt Hospital on March 17, 1888, in a very stupid condition. All that could be learned was that he had been sick for about three days. He was poorly nourished and anæmic; no sign of paralysis; pupils normal. Temperature, 105.8° F.; pulse, 130. During the night he was very restless and had to be tied down; vomited several times; passed urine and fæces involuntarily. The next morning his fever had abated somewhat, but his mental condition remained the same. On the 19th a partial left hemiplegia was noticed, and he frequently expectorated a brownish fluid. He failed rapidly, notwithstanding liberal stimulation, and died at 8.15 P.M.

Autopsy, by Dr. Delafield, nineteen hours after death. "Body fairly nourished. Brain, some increase of serum and some venous congestion. Old opacities of pia, more marked on left side. Brain normal. Lungs congested. Heart, old pericardial adhesions. Mitral valves have recent vegetations along margins. Aortic valves normal. Liver congested. Spleen, large and soft; contains some small infarctions. Kidneys, rather large, studded by a number of foci, apparently embolic. Stomach normal. Small intestine normal."

At the close of the autopsy, as no source of infection had been discovered, it occurred to Dr. Roosevelt, who was present, to examine the man's urethra, for any sign of inflammation. To his satisfaction, on squeezing the penis sufficient pus was obtained to make several cover-glass preparations and to inoculate some gelatine tubes. These, together with portions of the various organs, were sent to the Pathological Laboratory of the College of Physicians and Surgeons for examination.

Through lack of time the cultures were neglected and died before any observations were recorded, so that nothing determinate came of them. The cover-glasses and portions of the organs were, however, saved, and it is the result of their examination which I desire to report to-night.

[1] Read before the Anniversary Meeting of the New York Pathological Society, January 9, 1889.

Microscopical examination of the mitral valve shows, besides the old connective-tissue proliferation of chronic endocarditis, recent infiltration of the substance of the valve with small round-cells and fibrin, together with erosions on the surface of the valve, covered with fibrin and teeming with micro-organisms. These last are of two forms, micrococci and bacilli. The micrococci are by far the more numerous and are arranged in clusters and in chains; both varieties retain the stain when Gram's method is employed. The bacilli are slender rods, about four times as long as broad. They are in very small numbers and stain by Gram.

In the liver there are occasional foci of broken-down tissue, each of which is surrounded by a zone of tissue densely infiltrated with small round-cells. In these small abscesses micrococci are readily to be seen when stained by Gram's method. Besides lying loose in groups and chains in the abscess-cavities, occasional masses of micrococci are occluding small blood-vessels surrounded by areas of more or less necrosed tissue. The liver shows also some congestion and fatty infiltration.

The splenic tissue is very soft and engorged with blood. Emboli of micrococci occlude many of the small arteries.

It is in the kidneys, however, that the most pronounced changes have occurred. The blood-vessels in many parts are much distended by blood. Large areas of degeneration of the epithelium of the tubules are present, and scattered here and there over the surface of the kidney are small abscesses, in the centre of which there are groups of micrococci. Emboli of micrococci are to be seen in the interlobular arteries, in the vasa recta, and in the vessels of the glomeruli. The micrococci are morphologically identical with those in the liver, spleen, and vegetations on the mitral valve. They stain by Gram's method.

The lesion in the urethra is of a catarrhal nature. The epithelium is swollen and detached from the basement membrane. In places, the desquamated epithelium is heaped up in considerable masses, and in these masses are small clusters of micrococci in clusters and chains, which stain by Gram's method and are similar, morphologically, to those found in the internal organs. None of them are present in the deeper parts of the penis, nor is any lesion in the corpus spongiosum apparent. No undoubted gonococci have been seen.

The pus obtained from the urethra at the autopsy is teeming with micro-organisms. A few of these resemble gonococci very closely, being small diplococci, flattened on the adjacent sides, occurring both in the desquamated epithelium and free, and staining with fuchsin. These are not visible in the specimens stained by Gram's method, and in this point correspond with Neisser's gonococcus. Large numbers of other micrococci are to be seen everywhere through the pus. They are in clusters and short chains, and stain by Gram's method. Measurement shows these micrococci to correspond closely in size to those in the internal organs. They are not all of exactly the same size, but average about .9 micromillimetre in diameter.

As the result of the study of the specimens, the details of which have just been given, it is thought that the malignant endocarditis, with its attendant lesions in the other organs, may be attributed to the presence of staphylococcus pyogenes aureus and streptococcus pyogenes, and that it is not unlikely that these micro-organisms found entrance into the general system through the urethra.

The numerous and frequent complications and sequelæ of gonorrhœa have made it evident that the urethra may be an important site of inoculation of the general system. As far back as Lasègue's time the joint affection in gonorrhœal rheumatism was known to be a suppurative arthritis, and in 1880 Haslund [1] further directed attention to the marked differences between articular rheumatism and the gonorrhœal complication. The discovery of the gonococcus, and the fact of its presence in the pus of gonorrhœal joints, determined by Petrone,[2] Kammerer,[3] Smirnoff,[4] and Hartley,[5] remove all doubt as to the nature of the trouble and the source of the infection. This is a striking example of infection of the system from the urethra, but others are equally so: for instance, complicating epididymitis and orchitis, and suppurating buboes; abscesses in the prostate and Cowper's glands.

That a non gonorrhœal urethritis occasionally occurs is coming to be quite generally recognized. These cases are usually of short duration, and gonococci are absent in the discharge. Bockhart [6] has described a micrococcus, differing in many respects from the gonococcus, as occurring in this form of urethritis.

Again, the possibility of *mixed* infection has been attracting attention, and there are now a number of cases on record of this nature. Bumm [7] found the pyogenic bacteria to be the most frequent cause of these mixed infections. That such cases should occur is not strange, considering that Lustgarten and Mannaberg [8] have described eleven varieties of micro-organisms as occurring in the normal urethra, and among them staphylococcus pyogenes aureus. Bockhart [9] details two cases of such mixed infection; in one there was a suppurating bubo, in the other a peri-urethral abscess. In both cases gonococci were absent from the pus of the abscess-cavities, and staphylococcus pyogenes aureus was present in large numbers.

The literature of malignant endocarditis and pyæmia is not devoid of cases in which the source of infection seemed to lie in the urethra. In a somewhat hasty review of the literature since 1880, I have come upon the following: In that year Schedler [10] reported a case of malignant endocarditis following gonorrhœa, in which gonorrhœal joints complicated and, seven months later, were thought to be the source of infection to the heart. The patient died about a month after the involvement of the heart. In 1881 Weigert [11] called attention to the frequency of lesion of the male genitals in pyæmia; of 17 cases of pyæmia examined, 8 had lesion of the genitals (abscess of the prostate, vesiculæ seminales, etc.). He does not, however, allude to the lesion in the genitals as the source of the systemic infection. The same year a case of pyæmia secondary to gonorrhœa was described by Holst.[12] In this case, also, gonorrhœal joint trouble was present. Two years later (1883) Petersen [13] published an interesting résumé of 975 cases of gonorrhœa treated at the Alexander Hospital in St. Petersburg. Of these 537 were complicated cases, in two of which the complication was peri-urethritis, with pyæmia as the cause of death in one of these. In 1884 Dérignac [14] cited a case of endocarditis secondary to gonorrhœal joint affection.

This case recovered. In Paget's [15] investigation (1886) of 500 cases of pyæmia, 97 were thought to depend upon lesion of the genito-urinary organs. As Paget does not cite the cases in detail it is impossible to learn how many of them were dependent upon gonorrhœa. Unquestionably two of them were thought to be, for on consulting an article by Savory in St. Bartholomew's Hospital Reports, vol. iii. (1867), to which Paget refers as the source of 133 of his cases, I find these two attributed to gonorrhœa alone. Besançon [16] in 1886 reported two cases of malignant endocarditis in which lesions in the genito-urinary organs, which originated from the urethra, were thought to be the source of general infection. In the first of these, old suppuration of the seminal duct and epididymitis were found at the autopsy; in the second, abscess at the neck of the bladder, behind old strictures. In both cases pyogenic bacteria were obtained from the various lesions. In 1887 Lancereaux [17] added two cases to the list. In both malignant endocarditis was secondary to disease of the genital organs; in the one case of the prostate, in the other of the testicle. In the same year Van der Velden [18] described two cases of acute endocarditis secondary to gonorrhœa. Although both lived, there was thought to be no doubt as to the relation of the two affections. Recently Roswell Park [19] has reported a case of pyæmia thought to have resulted from gonorrhœa. The etiology of the case is somewhat obscured because of an old abscess at the sterno-clavicular articulation.

There are, then, on record at least nine cases of malignant disease, be they classified as cases of pyæmia or of malignant endocarditis, in which the urethra appears to have been the point of entrance of the micro-organisms. In none of these cases, so far as I am able to learn, were any cultures made, and, in so far, the proof of the etiological relation between the two affections is lacking. The morphological identity of the micro-organisms, in the cases examined, in the lesions of the genital organs and in those of the internal organs, certainly points to a connection between the two. It is somewhat difficult to conceive of a urethritis as resulting from a malignant endocarditis, and that the two lesions should be mere coincidences, without closer relation, in so many cases, though perfectly conceivable, seems to me improbable. In our case the fact that, though carefully looked for, no other point of infection was found, strengthens the theory that the urethritis was the primary lesion. It is a pity that no statement of the duration of the urethritis could be obtained *ante mortem*, as much light might have been thrown upon the case by it.

Our knowledge of the etiological relation between urethritis and malignant endocarditis and pyæmia may be summarized as follows:

1. Pyæmia has been shown by the investigations of Rosenbach [20] and Passet [21] to be due to the presence of the pyogenic bacteria—staphylococcus pyogenes aureus, albus, and citreus, and streptococcus pyogenes.

2. Micro-organisms belonging to this same class have been found in the valvular lesion of malignant endocarditis by Wyssokowitsch,[22] Weichselbaum,[23] Ziegler,[24] Prudden,[25] and others, and experimental endocarditis in animals has been produced by the above-mentioned writers and by Ribbert,[26] by the inoculation of the same micro-organisms.

3. The complications of gonorrhœa are very numerous, and for their explanation the possibility of introduction of micro-organisms into the general system must be presupposed.

4. In certain cases of mixed gonorrhœal infection of the urethra, pyogenic bacteria have been found along with the gonococci (Bumm,[7] Bockhart [9]).

5. Nine cases are on record in which malignant general infection occurred in patients suffering from gonorrhœa, and in some of these (Besançon,[16] Lancereaux [17]) micro-organisms morphologically identical with the pyogenic bacteria have been found in the urethral discharge as well as in the lesions in the internal organs. In these nine cases the urethra was the only discoverable point of infection.

The case which has been reported is thought to be another of the same nature. Whether the coincidence of the urethritis and the general disease be merely accidental, or whether the one bears an etiological relation to the other, is the question. There is certainly no inherent impossibility in the idea that infection should find entrance to the system through the urethra. Why should not ulcerated urethral mucous membrane offer as good opportunity for the entrance of micro-organisms as ulcerated mucous membrane in other parts of the body? It remains only for some intelligent investigator to prove it in a few cases by a careful study of the micro-organisms found in the various lesions in pure cultures.

ANTIPYRINE RASHES.—At a meeting of the Southeast Hants District Medical Society, Dr. C. C. Claremont read a paper on "Antipyrine Rashes," in which he described two cases which had occurred during the course of enteric fever. In the first, ten doses of fifteen grains had been given in the course of ten days, when the eruption appeared. It came out simultaneously on the abdomen, thorax, back, and limbs in the form of papules, darker, larger, and more solid than the spots of enteric fever. There was a considerable resemblance to measles. The eruption developed into enormous erythematous blotches, with much infiltration, their vivid red color being removed by pressure, leaving faint yellow pigmentary discoloration. The rash began to subside on the sixth day, and on the tenth day was only represented by faint coppery maculæ, resembling an old syphilitic eruption. Antipyrine was omitted on the appearance of the eruption. In the second case, the drug had been given in fifteen-grain doses, generally twice a day, and omitted altogether for four days. The enteric exanthem had been unusually copious. On the twentieth day of the exhibition of the drug, there was a papular erythematous rash on the extensor surfaces of the arms; this spread to the flexor surfaces, and also affected the calves. The antipyrine was omitted. On the fourth day the rash had almost gone, leaving only slight redness and desquamation. The patient had a relapse of fever, and was again treated with antipyrine without suffering from a return of the eruption. Dr. Claremont stated that antipyrine rash generally was of the papulo-erythematous type, and began on the extensor surfaces of the elbows and knees. It had been described in one case as commencing on the face, and in another as extending to the mucous membranes. Once vesicles had been present. Its most constant characters are its bilateral symmetry and its duration of about five days, irrespective of the continuance or withdrawal of the drug. The entire absence of subjective symptoms was exceptional. A scarlatiniform rash had been mentioned, but Dr. Claremont had been unable to ascertain that it was more than a transient flushing, such as is produced by belladonna.—*British Medical Journal.*

Clinical Department.

ABSCESS OF THE LUNG FOLLOWING THE RETENTION OF A NAIL IN THE BRONCHUS FOR A YEAR.[1]

By HOBART CHEESMAN, M.D.,

NEW YORK.

GEORGE B——, three years of age, was brought to me on September 25, 1888, having coughed up a nail the evening before. He was pale, emaciated, and feeble. The skin was hot and wrinkled, but moist with perspiration; the breath was very offensive, and there was being constantly coughed up a very fetid, purulent secretion, most of which was swallowed. Physical examination showed dulness in the middle and lower portions of the right lung, and numerous moist râles of various volume, together with tubular breathing, were audible in this region. The mother gave the following history, which was afterward corroborated by the father, as well as by several of the neighbors. About a year ago she had given, one day, the child a hammer and a nail, like the one coughed up, to play with. He was thus sitting on the floor when, beginning to cry and cough, she discovered that the nail had disappeared and that the child was struggling with something in its throat. The coughing and gagging continued for some time, and quite a little bloody matter was coughed or vomited up. After a few minutes the coughing mostly ceased for the time; but from this date the child began to be troubled with a cough which never entirely left him. At times it would continue very severe for days or weeks, and then there would be an interval of comparative relief and the general health would be good. After six or eight months had thus elapsed, it began to be noticed that the breath and sputa were offensive, and fever and sweating were also observed. Since then the patient had grown by degrees more emaciated and feeble, and the paroxysms of cough had become very violent and distressing. While the child was in one of these paroxysms the father lifted it by the legs, the head dependent, slapped its back between the shoulders rather vigorously several times, and with some impatience and desperation at the constant annoyance, and with a vague idea of aiding the child in what appeared to be efforts to expel something from the lungs. Upon putting him down the child appeared to be struggling with something in his throat, and the father, inserting his finger, extracted from it a nail, which was covered with a thick coating of iron rust and mucus. It was originally tin-plated. It measured an inch and a half in length, was cylindrical, with a sharp pencil-point, and a circular head five lines in diameter.

After the expulsion of the nail the paroxysms of cough were less violent, but pus continued to be expectorated in connection with the symptoms of septicæmia, and at the end of three weeks the patient died. The case is, unfortunately, incomplete from lack of an autopsy.

Poulet quotes an autopsy by Leuret on a lunatic, in which the right lung was normal except that there were some adhesions to the costal pleura. The left lung, however, was extensively adherent to the costal pleura, was hepatized and filled with tubercles, the majority of which were softened, and the lining membrane of the bronchial tubes was red and thickened. The trachea contained a nail an inch and a half long, the head of which was engaged in the left bronchus. The wall of the bronchus, which had been in contact with the head of the nail, was ulcerated and its inner layer destroyed; the nail was covered with mucus and oxidized. Autopsies in other cases in which foreign bodies of different kinds have lodged in the tracheæ or bronchi, and remained for considerable time, have shown that, in consequence, hepatization and cavities have resulted without the presence of tubercles, the cavities being simple abscess cavities. Such, probably, was the condition in this case. In many cases supposed to be of this nature, after expulsion of the foreign body, either spontaneously or by surgical operation, recovery has taken place. But in other cases of this character, where extensive local changes and profound constitutional disturbances have occurred, as in this case, death has resulted, notwithstanding the removal of the original cause.

It is not very uncommon, as is well known, for foreign bodies, such as pieces of bone of considerable size, to remain in the tracheæ or bronchi for many years, tolerance in the course of time, having been established, after which very little disturbance was occasioned by their presence. Sometimes in such cases, after years of tolerance, symptoms have recurred, resulting in the expulsion of the foreign body or in death. This is explained by supposing that the foreign body which, during the period of tolerance had become embedded or fixed, is again freed by ulceration of the enclosing tissues. Whether in the case before us the nail had all the time remained free, and was only waiting the classical procedure, to which accidentally the father finally resorted, to expel it, is, more or less, a matter for conjecture.

Foreign bodies, primarily embedded in the œsophagus, have been known to find their way by ulceration into the bronchi (Poulet); but such instances are rare and are accompanied by œsophageal symptoms. No such symptoms occurred in this case. The patient continuing to have a good appetite most of the time for several months following the disappearance of the nail, swallowed solids and fluids without appreciable difficulty from first to last. From this fact, and from the primary symptoms which have been described, it seems altogether probable that the nail found its entrance through the larynx, either at the instant or during the act of vomiting immediately following the accident.

One peculiar circumstance of the case is that the parents not once thought of connecting the cough, which began at that time and continued uninterruptedly during the whole year following, with the disappearance of the nail, until the father unexpectedly extracted it, as described, from the patient's throat. Several physicians at different times are said to have examined and treated the patient, in the meantime no one of whom ever expressed a suspicion of the nail as the cause of the cough. The child had always been robust and well previous to the accident, except that it had once had what the mother supposed was inflammation of the lungs, but from which it promptly and perfectly recovered several months prior to the accident.

MATERNAL IMPRESSIONS.

By A. B. LEGGATT, M.D.,

BABYLON, N. Y.

THE cases reported by Dr. R. Gross, of Eureka, Cal., describing the effects of maternal impressions are not unusual, although they appear to be doubted by some. Practitioners in the larger towns and cities are often called upon for surgical aid in such cases, but it is the rural physician who sees a large majority of them at birth. It is no secret that dentists decline to extract teeth for women while *enceinte*, if they are aware of their condition, for fear of hare-lip in the child. It is also a recognized fact that domestic animals are influenced in the same way. Horse-breeders too often take advantage of that fact, and obtain colts that can be sold as the get of a valuable stallion to which they are not related.

The following cases occurred in my former practice in a farming community during twelve years, and within seventy miles of New York. Mrs. M——, a young farmer's wife, was kicked by a cow that she was milking. Her upper lip was cut entirely through, and one upper incisor tooth was loosened. Six months after she was delivered

of a female child with hare-lip. Mrs. S——, a farmer's wife, mother of two healthy children, went into the fields after berries. One shoe—the right one—was run down at the heel, so that she walked all day on the outside of her foot, and subsequently had a swelled ankle. Eight months after she gave birth to a female child with club-foot (*talipes valgus*) on the right side.

The following case happened in the practice of a medical brother in the same town, the subject of which is now a middle-aged man. A farmer's wife went to a spring for water very early in the morning. A huge bull-frog which lived in that spring had been on a nocturnal excursion and was returning home. He made his last jump for the spring, but instead landed in the woman's lap. She ran screaming to the house, and remained in an hysterical condition for hours afterward. Nearly nine months after, she was delivered of a male child that had a strong resemblance to a frog. His arms stand out from his body and his legs are flexed at the hip and knee, his head is turned back on his shoulders and his eyes are bulging. He walks partly erect with the aid of two canes. Mentally, he is quite intelligent.

Any country practitioner can furnish a list of cases like the above, with variations, and his only surprise will be that his city brother has not informed himself on the subject.

THE CURETTE IN PUERPERAL ENDOMETRITIS.

By C. M. HANSEN, M.D.,

CROOKSTON, MINN.

In The Medical Record of January 12, 1889, I read Dr. Grandin's plea for "Active Treatment of Puerperal Endometritis by the Curette," and the discussion about it in the Medical Society of the County of New York. I suppose most physicians will use the curette in cases of puerperal endometritis, when we know that pieces of membranes or of placenta are left inside the womb. Now Dr. Grandin goes farther, and, comparing the inside of the womb with the surface of a surgical wound covered with sloughing granulations, advocates the use of the curette in any case of puerperal endometritis, when it is caused by infection, without anything left of the placenta. Dr. Grandin will meet with some opposition on this point, mainly based on the fear of loosening the thrombi in the venous sinuses and opening new ways for infection; and I know that many of us in private practice hesitate in using the curette if we are sure that no portion of the placenta is retained. I had the same fears myself until my opinions were changed by a case in my practice, the history of which I give here as a clear case of septic infection of the endometrium treated by the curette, and, I hope, as an illustration to Dr. Grandin's paper.

Mrs. M——, aged thirty-two, married, had a miscarriage while stopping over in this town, June 29, 1888. She had given birth to one child, now aged five years; had since suffered from retroflexion of the womb, and had had frequent miscarriages, always in the first months of pregnancy. This last abortion, to which no doctor was called, occurred in the morning, and a fœtus in the third month with a complete placenta was expelled; there was insignificant bleeding and all would have been well if her husband had not been something of a domestic doctor, and a "meddlesome" one, too. In the evening after the abortion he gave her an injection of carbolized water through a common vaginal syringe, the nozzle of which he carefully managed to get through the open orifice into the cavity of the uterus. Hardly an hour afterward the woman had a chill and began to feel ill, had severe abdominal pains, and could not sleep all night in spite of the free use of opium. As she got worse steadily, I was summoned the next day. I found her pale, suffering from incessant pains in the lower part of the abdomen. Temperature, 104° F.; no peritonitic symptoms. By exploration the uterus was found retroflected, slack, large, and heavy. Considerable pain was excited by touching the fundus; no parametritis. The orifice opened sufficiently to admit a finger. No bleeding since the abortion; very little discharge now, but of fetid odor. She inhaled a few drops of chloroform, and was placed on her back, and after insertion of Sims' speculum, fixing of the cervix, and thorough cleansing of the vagina, I explored the uterine cavity with the finger, but found so far no loose pieces nor blood-clots. Then I irrigated with hot water, and scraped the whole inside with a large-sized curette. After scraping, I introduced, as usual, the uterine probe, wound with cotton and soaked in tincture of iodine. After these proceedings the patient went to sleep, and made a rapid and complete recovery, her temperature being normal the evening after the operation. By the scraping were removed only fresh and necrotic granulations, and by careful examination no trace of fœtal membranes nor of placenta were found in it. An interesting point in this case is, it seems to me, that the very moment of infection is known. The abortion may have been caused by the retroflexion of the womb, or may have been artificially induced, but the infection was surely brought by the nozzle of the vaginal syringe.

Allow me, at last, a suggestion, which I do not find mentioned in the paper nor the discussion. When endometritis sets in, the uterus becomes slack, and in this condition the use of the curette may be more difficult; therefore I would propose to begin the operation by gentle massage of the fundus uteri through the abdominal wall, until the womb is sufficiently contracted. A few drops of chloroform will in this case generally be needed. I would recommend the use of the largest curette possible, not only to get the work done thoroughly and in short time, but also for the sake of safety. If there is any danger in curetting a soft-walled uterus, the danger is surely less the larger the size of the curette.

LARGE DOSES OF CALOMEL IN PNEUMONIA AND CROUP.

By E. T. STRONG, M.D.,

ELIZABETHTOWN, N. Y.

In the winter of 1885 and 1886, I was led, by an editorial in The Medical Record, to try large doses of calomel in croupous pneumonia. The results were so good that I have continued to use it, the number of my cases being now about twenty. All were in the stage of exudation, with high or rising temperature. In age they ranged from eight to over sixty years. In severity, from cases which would have recovered under any treatment, to those that I considered desperate. In every case there was immediate improvement in temperature, respiration, and heart's action, subsidence of the disease in twenty-four hours, and, with one exception, rapid recovery, little or no stimulating or medication being needed. The exception was under most unfavorable surroundings, but was apparently convalescing, when purpura hemorrhagica set in, and the patient died from nasal hemorrhage. My usual and smallest dose was twenty grains every three hours, in most cases continued twenty-four hours. In one case, which I believed would be fatal, the patient took an initial dose of sixty grains, and thirty grains every three hours, until she had taken three hundred and sixty grains. There was no ptyalism in any case, and but moderate catharsis. One of the most remarkable features in every case was the rapid improvement in the heart's action.

I tried the same plan in three cases which I diagnosed as membranous croup. In two, the diagnosis was confirmed by expectoration of shreds of false membrane. In one of these patches of exudation were visible. In the third, an infant of nine months, I was unable to confirm the diagnosis.

All were reported as improving in breathing before the second dose, and all made a rapid recovery. I gave to an

infant eighty grains, in ten-grain doses; to a boy aged six years, one hundred and sixty grains, in twenty-grain doses; and to a boy of twelve years, only eighty grains in four doses. I never before had three consecutive recoveries from croup.

These few cases are not enough alone to prove the utility of the remedy, but at least they have convinced me that I can safely give, in similar conditions, doses that a few years ago I should have thought reckless.

SIMPLE HYPERMETROPIC ASTIGMATISM OF HIGH DEGREE.

By S. MITCHELL, Jr., M.D.,
HORNELLSVILLE, N. Y.

The following case presents some rather unique features. One being the high degree of hypermetropic astigmatism and the very slight asthenopic symptoms produced thereby. Gertrude C——, aged sixteen, a bright, active miss, of nervous temperament, but in perfect health, came to my office February 9, 1889, to consult me about her eyes; not because they gave her any serious trouble, but because the mother, who accompanied her, wished to know why her daughter was compelled to hold what she was reading in such close proximity to the eyes. Headache, or pain in the supra-orbital regions or about the temples, was not complained of, nor had there ever been any blepharitis, succession of styes, or any of the numerous affections of the lids, such as frequently accompany an eye strain. The mother informed me that a travelling optician (?) had at one time examined her daughter's eyes with the idea of fitting her with glasses, but for some reason did not, although he informed the mother that her daughter was "*probably* astigmatic." My first examination showed R. V. $\frac{20}{100}$, which was rendered worse by the weakest convex spherical lenses. With a +2 D. cyl., axis 90°, vision was $\frac{20}{40}$. L. V. $\frac{20}{40}$ was also made worse by convex sphericals, but with a +1.5 D. cyl., axis 90°, vision was $\frac{20}{40}$. At a second examination, two days later, both eyes being under atropine and accommodation fully suspended, vision was as follows: R. V. $\frac{20}{100}$ with a + 4 D. cyl., axis 110°= $\frac{20}{40}$. L. V. $\frac{20}{40}$ with a +3.5 D. cyl., axis 90°= $\frac{20}{40}$. By retinoscopy the illuminated portion of the retina appeared as a bright band extending vertically across the pupillary area, in which the vertical blood-vessels with a bright reflex were plainly visible, 30 inches from the eye. And of course it is almost needless for me to remark, that by rotating the mirror of the ophthalmoscope upon its vertical axis, the shadow moved quickly in the opposite direction from the rotation of the mirror; while if the mirror was rotated upon its horizontal axis there was no perceptible movement of the shadow. With the lenses above indicated, viz., a + 4 D. cyl., axis 110° before the right eye, and a + 3.5 D. cyl., axis 90° before the left eye, the direction of the movement of the shadow was not changed in either eye, although its movement was very much slower. Showing that even these lenses did not correct the whole error.

At the third examination, accommodation being fully restored, my patient's vision was best improved by the same lenses indicated, while the eyes were under atropine, giving her vision of $\frac{20}{40}$ with both eyes, and able to read J. No. 1 at 8 and 30 inches. Contrary to the ordinary rule, I did not deduct 1 dioptre in ordering the above glasses, but gave the full correction, which are now being worn with perfect satisfaction.

ALBINISMUS.

Dr. W. H. Dudley, of Newport, N. Y., writes: "The condition of albinism is one of such rarity that I am led to report two cases occurring in one family in this vicinity. The subjects are, a boy, aged about four years, and a girl baby, less than one. My attention was called to the boy by his father, who asked what could be done for his eyes, which he remarked were weak. His eyes presented the appearance of continual nystagmus and hippus when directed toward the light, which made him present the singular appearance so often given in descriptions of albinos. The irides are so devoid of pigment that the red reflex of the retinæ show through them to that extent, giving them almost the same appearance seen in the eyes of white rabbits. The eyelashes, eyebrows, and hair present the same colorless appearance as the skin which is entirely devoid of pigment.

"The parents are both of Irish extraction, well built, and have always enjoyed excellent health. While both parents have light complexions, their hair is dark chestnut, and eyes blue. All four of their grandparents, until recently, were alive, and nearly or quite eighty years of age, enjoying a comfortable degree of health."

Progress of Medical Science.

A New Method of Ophthalmoscopy.—Dr. Bellarminoff, of Moscow, recently demonstrated to the Berlin Medical Society a new method of ophthalmoscopy (*British Medical Journal*). The eye is first made insensible by cocaine; then a little plain glass is pressed against the cornea. Between the glass and the cornea a very fine zone of fluid is instantly formed. Thus glass, fluid, and cornea being transformed into one refracting medium, the refracting power of the cornea is wholly eliminated. The eye is thus transformed into a highly hypermetropic one. By this method it is very easy to see the fundus of the eye, and four or five persons can examine the eye at the same time. The method is likely to be of great service for the instruction of students, but it is not probable that it will be of much use to practitioners. Though new in its application to human beings, the method has, we believe, been suggested before, and tried upon lower animals.

Pathogeny of the Complications of Scarlatina.—Dr. Raskin has published some investigations he has made on the source of the malignant complications of scarlatina. In uncomplicated cases of the affection he has never been able to detect streptococci in the blood or, in fatal cases, in the organs (*The Lancet*). Streptococci never appear in the skin, and they were only found in two cases out of eighteen in the desquamation. These streptococci, when inoculated into animals, only produced the ordinary results of streptococci obtained from other sources. It is, he says, probable that such complications as inflammation of the glands, phlegmonous cellulitis of the neck, suppurative, and perhaps serous, inflammations of joints, broncho-pneumonia, and purulent otitis are due to a secondary infection by means of chain-like cocci. It is not possible to say the same regarding diphtheria. Though streptococci are found very constantly in diphtheritic membranes, they are not generally admitted as having a causal relation to the disease. Dr. Raskin has also never been able to succeed in inducing diphtheria by inoculating mucous membrane or the raw surface of sores with streptococci; a specific form of bacillus has, moreover, been found in diphtheritic tissues by Löffler and other observers; and it is difficult to understand how the same micro-organism (a chain coccus) can set up two such different diseases as diphtheria and suppurative inflammation. According to the author's researches, secondary suppurative processes are set up by chain cocci, which may or may not be associated with other micro-organisms—staphylococci in otitis, and micrococcus pyogenes tenuis in pyæmia. These organisms enter the system through the scarlatinal ulcers of the throat, and make their way to distant parts by means of the lymphatics. There are two especially favorable conditions in existence—the readiness of these bacteria to travel along the lymphatics, and the richness of the pharyngeal tissues in these vessels. When streptococci enter the blood they

are disposed of in three different ways: (1) they may rapidly die and disappear without producing any further disturbance than some degree of pyrexia; (2) they may emerge from the vessels into the organs, and there set up suppurative changes; and (3) they may set up pyæmia and cause death. The morphological and biological relations of the streptococci examined did not differ from those of other streptococci. The practical advice which Dr. Raskin is led to give is to keep the mouth and the throat particularly clean, to be very careful as to the cleanliness of everything that is introduced into the mouth, and, to make assurance doubly sure, to use disinfectants.

Phosphorus Necrosis.—Dr. Magitot read a paper recently before the Paris Academy of Medicine, on phosphorus poisoning, and particularly phosphoric necrosis, of which the following is an abstract (*The Lancet*): Owing to the number of accidents that have occurred, many of which were fatal, among the workpeople engaged in the manufacture of lucifer matches, and the Prefect of Police having applied to the Council of Hygiene for its opinion and advice, Dr. Magitot was charged to report on the subject. The author reviewed the inquiries undertaken during the last forty years by divers physicians and hygienists, and cited the attempts that have been made to remove the dangers incurred by the working-people in phosphorus manufactories, and particularly those of lucifer matches, but which have proved of no avail, as shown by the continuation of the accidents. In the second part of his report, Dr. Magitot studied the pathogeny of these affections, such as intoxication, action on the respiratory passages, and particularly the necrosis which mutilates or kills the workmen. According to a large number of observations in France and elsewhere, the author believes himself justified in regarding as inseparable from the production of necrosis the penetration of the irritating vapors of phosphorus through dental caries, of a kind which he designates under the significant name of "penetrating caries." It is an exclusive pathogeny, which Dr. Magitot claims to prove the value of by the facts which he had collected, and which is in contradiction with the ancient theories which he refutes, viz., that of the Germans, or the theory of the elective action of phosphorus on the bones (Lorinser), and that of the gingival and periostic medium defended by MM. Trélat, Lailler, etc. The following prophylactic measures are proposed by Dr. Magitot in view of preventing the accidents attending the manufacture of phosphoric substances. These are the perfecting of the means of ventilation, the isolation of the different departments of the manufacture, and the suppression or the neutralization of the phosphoric atmosphere of the workshops. For the individual hygiene of the workmen the following rules should be observed. The interdiction of the entrance to the manufactory of all individuals whose health or constitution is defective, and particularly if they are suspected of being threatened with necrosis, as may be judged by the state of the mouth, and the immediate dismissal of all persons bearing predisposing lesions. Under these conditions M. Magitot affirms that, in anticipation of the realization of the wish, so often and so fruitlessly expressed, for the substitution of red phosphorus for white, we may certainly and radically realize the suppression of all danger for the workmen, and, in particular, that of phosphoric necrosis.

The Rational Treatment of Strictures of the Male Urethra.—In a communication published in *The Post-Graduate*, Dr. J. H. Girdner states that, "The so-called gradual dilatation treatment is a misnomer as applied to strictures of the penile portion. It conveys only the idea of stretching, while the most important element in it is the pressure it exerts on the connective tissue surrounding the tube. One of the simplest and best known laws of nature is that pressure on a part causes absorption. We, therefore, take advantage of this law, and of the fact that the tissues around the penile portion of the tube are comparatively firm, and offer a certain amount of counter-pressure. It is his rule, also, to aid this counter-pressure by allowing each instrument to remain in the urethra for five minutes or more, and during this time to make gentle but firm pressure over the seat of the stricture by squeezing the penis at this point between the thumb and finger, carrying the manipulation all around the organ. In cases in which the deposit of cicatricial tissue was so large that it could be felt as a small, hard tumor around the point of stricture, he has been able to note its gradual disappearance from day to day under this treatment. After much experience with this method, he has yet to see a stricture of the penile portion which failed to yield to it, and when dissipated in this way the stricture has not returned in two, three, and five years after all treatment was discontinued, as is proven by some of his own cases. This he holds to be the only rational and successful treatment of strictures in the penile portion. With regard to stricture of the deep urethra, the author says that, gradual dilatation and pressure, so successful in the penile portion, will cure only a limited number of strictures when they are situated in the bulbous and membranous portions. The reasons for the failure are, because strictures in these portions are, as a rule, very tight, the open space around the tube here allowing of a large deposit of connective tissue; and, furthermore, this same laxity of the surrounding tissues prevents us from getting the counter-pressure, when solid sounds are passed, which the more compact tissues around the penile portion offers, and the location of the tube here also prevents us from making counter-pressure by proper manipulation, which we found so useful in the penile portion. Except, therefore, in cases in which the stricture is of recent formation, with only a small amount of cicatricial tissue opposite the point, gradual dilatation and pressure will prove, at best, only palliative in strictures of the deep urethra. Perineal section, or external urethrotomy, is an operation almost entirely void of danger, and, when properly performed, it may always be depended upon permanently to cure strictures in the membranous and bulbous portions of the urethra. It has been so successful in my hands that I have come to feel justified in promising my patients a permanent cure in ten to fourteen days from the date of the operation. External urethrotomy is free from the dangers and inconsistencies of the internal operation. Its proper performance contemplates and accomplishes the most simple and rational means of relief, which is to incise externally the urethral wall at the point of constriction, and introduce into the incision a wedge of sound tissue sufficiently large to restore the tube to its normal calibre. It is not difficult to accomplish this. His rule is to cut in the centre of the perineum, reach the stricture, freely incise it, cutting into the sound tissues on both sides for a fourth or half an inch; then pass from the meatus to the bladder a hard rubber catheter of the size of the normal urethra, and tie it in position. This causes a gaping of the walls of the incision, and prevents their primary union. The extent of this gaping is the correct measure of the wedge of sound tissue which is to be introduced into the circumference of the tube. This wedge is secured by the final union of the granulations which, by thus keeping the walls apart, are made to spring up on the two walls of the incision. After thirty-six hours the catheter is removed and the urine allowed to drain from the bladder through the wound, and this, together with the daily passage of a sound of the size of the normal urethra, is sufficient to insure the formation of a proper-sized wedge of granulation tissue. Strict asepsis is, of course, observed throughout the operation.

Tincture of Iron in Bright's Disease.—Dr. Wyss employs the ethereal tincture of the perchloride of iron, in doses of ten drops three times a day, in the treatment of chronic Bright's disease. He reports a large number of cases so treated, in more than half of which the albuminuria rapidly and completely disappeared.—*Der Fortschritt.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 16, 1889.

THE INFLUENCE OF DRUGS ON DIGESTION.

A SUMMARY of the observations made by Fraser, Petersen, Gluzinsky, Roberts, Fowler, Eccles, and others, upon the interference of remedies with digestion, is given in the last issue of *The Dietetic Gazette*. Professor R. H. Chittenden, of Yale, has also gone over this subject in a very thorough manner in *The Medical News* of February 19th. Our present knowledge, therefore, of the influence of drugs in promoting or retarding gastric digestion is fairly complete. Some of the facts that have been thus collected are extremely important, and should be kept in mind in the ordinary prescribing of remedies.

Salivary or amylolytic digestion takes place best in a neutral medium, and during the first five to thirty minutes after ingestion of food. Amylolytic digestion also occurs in the small intestine by virtue of the pancreatic, biliary, and enteric diastase.

This digestion is helped (according to artificial tests) by minute doses of mercuric cyanide, by arsenious oxide, and ammonium arsenate, by small amounts of tartar emetic, potassium chlorate and sodium chloride, and of many of the bitter alkaloids like quinine and morphine.

Large amounts of almost any germicidal agent decrease the activity of starch digestion; the mercuric salts being especially active. Arsenious acid, strychnine, antipyrin, and antifebrin have a retarding influence.

The proteolytic or peptic-hydrochloric acid digestion, which takes place in the stomach, is also much influenced by various drugs. The ordinary and average percentage of HCl in the gastric juice is twelve per cent., but pepsin may act more energetically, according to Chittenden, in a less amount of acid.

Observers have found many more substances which retard peptic digestion than they have of those which accelerate it. Among the latter, arsenious acid and arsenic acid are especially mentioned. Paraldehyde and thallin in small doses increase peptic action, as does also sodium chloride.

Among substances that retard digestion are nearly all the metallic salts, including those of iron and mercury; the alkaline chlorates, nitrates, and sulphates, nearly, if not quite, all the alkaloids, including strychnine, quinine, atropine. Alcohol holds a peculiar position in regard to digestion. Says Professor Chittenden: "The results of many experiments have shown plainly that the presence of *alcohol* impedes the proteolytic action of pepsin, even though it is present in comparatively small quantity; but as Gluzinski has shown, alcohol rapidly disappears from the stomach, even 100 c.c. of twenty-five per cent. alcohol disappearing inside of fifteen minutes. While in the stomach, alcohol undoubtedly retards the solution of proteid matter. Schütz finds that two per cent. has a retarding action, while ten per cent. causes a very great retardation, and fifteen per cent. allows only a slight digestive action. Bikfalvi finds similar results, as do likewise Ogáta and Klikowicz. The disappearance of the alcohol, however, is followed by the secretion of an active, strongly acid gastric juice, which continues generally long after the food is entirely digested. Hence, under the influence of alcohol, there is often an accumulation of large quantities of fluid in the stomach, frequently colored yellow by bile. With small quantities of alcohol, therefore, especially with an abundance of food, there is an undoubted stimulation of proteolytic action, induced mainly, if not wholly, by the increased secretion of hydrochloric acid. Under such circumstances the first stage of retardation is hardly to be considered, since the alcohol disappears so rapidly. With large amounts of alcohol, the mechanical functions of the stomach are interfered with, and thus the food compelled to remain a much longer time in the stomach than normally."

Soda-water, carbonic acid water, tea, coffee, and spring water are found to have no appreciable influence on stomach digestion. It is to be borne in mind also that some of the drugs which cause retardation of digestion are very rapidly absorbed and may act in a measure like alcohol, promoting digestion indirectly after their absorption by stimulating the heart or nervous system.

The general conclusion, however, that one must reach from a survey of the work we have just been reviewing, is that medicines injure the stomach, unless carefully given. Thus the conclusions of science are quite in harmony with the common sense of mankind.

THE FREQUENCY OF LOBAR PNEUMONIA IN YOUNG CHILDREN.

IT is very commonly supposed that lobar pneumonia is a disease peculiar to adults and older children, and that it occurs very rarely, if ever, in infants or children under four or five years of age. So common, indeed, is this belief, that the term pneumonia in children is usually held to be synonymous with catarrhal or broncho-pneumonia. It is even said that the anatomical structure of the child's lung is such as almost to preclude the possibility of fibrinous pneumonia, or at least to predispose very strongly to the occurrence of broncho-pneumonia.

That the disease is less common in children than in adults is most certainly true, yet there are not wanting those who maintain that it is of much more frequent occurrence than is generally supposed. Dr. Guaita has recently published some statistics from his own practice which led him to conclude that true croupous pneumonia in infancy is not a rare disease (*Archiv für Kinderheilkunde*, vol. x., No. 1). Of one hundred and thirty cases of pneumonia occurring in children under three years of age, he reports forty-five which presented all the symptoms of the croupous variety. Unfortunately, however, he relied wholly upon the clinical signs for his diagnosis, not having had the opportunity of confirming this diagno-

sis by post-mortem examination, consequently his statistics are of comparatively little value in settling this disputed point.

At a meeting of the New York Pathological Society in October last (THE MEDICAL RECORD, December, 1, 1888) Dr. L. Emmet Holt reported a case of primary croupous pneumonia in a child two years of age, in which the diagnosis was confirmed at the autopsy. In the discussion following, Dr. Prudden said that he had seen but four cases of genuine acute lobar pneumonia in children, three years of age and under, in a large number of post-mortem examinations conducted by himself and Dr. Northrup with a view of studying the lesions of pneumonia in children.

Although possibly of no very great practical importance it would yet be a matter of considerable interest to determine positively the relative frequency of these two forms of pneumonia in infants and young children, and it would seem not to be a matter of great difficulty to do so, if the statistics of post-mortem examinations in children's hospitals were carefully studied.

HOSPITAL ACCOMMODATIONS IN NEW YORK.

AT the last anniversary of the Academy of Medicine the incoming president uttered some very sensible words concerning the adequacy of agencies existing in our city for the treatment of the sick. He showed that the supply is in some directions equal to the demand, and in other directions is in excess thereof. This is particularly true with walking cases. A man with a deformed chest can nowadays make a respectable living by hiring out to teachers of physical diagnosis at our many institutions. If a man have some rare disease there is a strife over his body to which the contention of Michael and the devil over the body of Moses affords but a faint parallel.

A few days after the address above alluded to appeared in the daily papers, a layman replied with a communication in which he denied the truth of the statement made concerning hospital accommodations. He instanced a case for whose admission he had applied to several hospitals, but in vain. His argument, therefore, seemed to have a basis of truth. In this particular case an explanation was easy. The patient presumably, from the account given, was suffering from chronic rheumatism, and it is very easy to see how our large institutions, with their active medical services, might have been unable to accommodate this particular case.

A review of the hospital and dispensary history of the last few years shows that the new institutions, instead of occupying fields of usefulness now vacant, have been made to needlessly duplicate existing agencies. The medical needs of Lenox Hill did not require the establishment of the Presbyterian Dispensary, nor those of the West side that of the Vanderbilt Clinic. Both regions were well supplied before. The same observation would hold true, though perhaps to a less degree, of other quarters of the city. There is in our large hospitals ample accommodation for all cases of acute illness. Infectious diseases are directed elsewhere. Our needs lie now rather in the direction of accommodations for chronic cases of a general nature. We should have a private institution for diphtheria cases. The initial step has already been taken in this enterprise. We need a large institution for phthisis cases—away from the heart of the city, and built, perhaps, on the small pavilion or cottage plan. But let us have at present no more dispensaries. We have enough now to supply the wants of double our present population.

THE PATHOGENY OF ADDISON'S DISEASE.

THE definition of Addison's disease is tolerably clear, but much confusion still exists in the minds of many as to the true nature and pathogenesis of the affection. As is known, it is a disease characterized primarily by a marked and constantly increasing weakness, not necessarily associated with any emaciation, pains in the epigastric and lumbar regions, sometimes shooting to contiguous parts, vomiting, and other evidences of digestive disturbance, a weak and small pulse, dyspnœa, and usually, though not invariably, a bronzing of the skin and mucous membranes. Associated with these symptoms there is some lesion in one or both, almost invariably the latter, of the suprarenal bodies. The dark coloration of the skin, although the most characteristic, is not the most constant symptom of the affection. It often does not appear until the other signs of the disease have existed for quite a length of time, and in a not inconsiderable proportion of cases it is absent throughout the whole course of the disease. This is due possibly, as Jaccoud has suggested, to the fact that it is a late symptom, and thus the patient may die from asthenia before sufficient time has elapsed for the pigmentation of the skin to take place. At the autopsy, however, in these cases the adrenals are found to be diseased, so that the affection is to be characterized as true Addison's disease, despite the absence of the bronze discoloration.

In a recent lecture (*L'Union Médicale*, December 27, 1888) Professor Jaccoud recalls the views which he expressed a score of years ago, and which, with some modifications, he still holds, concerning the pathogeny of the affection. It is not, he maintains, the lesions of the suprarenal bodies *per se* upon which the complex of symptoms depends, but rather upon the secondary changes in the semilunar ganglion and solar plexus resulting from these lesions. This portion of the sympathetic system, lying between the two adrenals, is directly affected by disease of the latter. The ganglia are sometimes found to be actually diseased, but often it is only in the nerve terminations in the adrenals that lesions exist. The cardiac and respiratory symptoms, and the epigastric pain, are explained by the connections existing between the pneumogastric nerve and the abdominal sympathetic. The bronzing of the tissues is the result, the author holds, of trophic disturbances dependent upon the sympathetic lesion. The pigmentation comes from the blood and occurs through the lesions of the adventitia of the arterioles, and even of the media as well as in the larger vessels. This explains the late appearance, or even absence, of the tegument discoloration. There is no peculiar lesion of the suprarenal bodies, Jaccoud maintains. It is usually a process resembling, if not identical, with tuberculosis, such as was described by Addison, but it may be of any other sort, even simple atrophy. The nature of the lesion is of little moment, the essential fact being some disease of the suprarenal bodies, leading to

changes in the abdominal sympathetic, with the fatally progressive symptoms depending thereon.

Addison's disease has usually been considered to be a disease of adult life, but this need not necessarily be the case. Instances have been reported in which there was discoloration of the skin in young infants, and at the autopsy the adrenals have been found to be diseased. The gross appearance was usually that of tuberculosis, though tubercules were not always found on examination under the microscope. But, according to Jaccoud, these are cases, nevertheless, of true Addison's disease, and accepting the views above referred to, there would seem to be no reason for regarding them in any other light. In accordance with this theory, age and the nature of the lesion are unimportant, the changes in the adrenals and the symptoms resulting therefrom constituting the affection going under the name of Addison's disease.

MEDICAL EXAMINING BOARDS AND MEDICAL COLLEGES.

After Virginia got her State Examining Board, one of the medical colleges of the State undertook to amend the law so as to exempt the graduates of State institutions from its workings. The college in question was justly subjected to criticism and ridicule. Now it seems that a similar move is being undertaken by one of the State medical colleges of Minnesota.

Such exceptions, it is easy to see, are simply asked in the interests, pecuniarily, of the local medical colleges, and if allowed would render the work of State examining boards a farce. If local medical colleges are afraid to have their graduates go before an impartial board, they had better go out of the business.

This movement on the part of certain medical colleges to secure exemptions for their graduates from the registration laws seems to be growing in popularity.

We trust that the Minnesota Legislature and profession will put a quietus on the efforts of the colleges in that State.

FREE WINTER BATHS.

Our Legislature seems to be in a generous mood with the public money just now, and we trust that some measures will be taken looking to the establishment of free warm baths for the poor population. If they need facilities for ablution in summer, much more do they in winter. In the warmer days most anyone can take some sort of a bath, even if he has only half a pail of water, but this is manifestly impossible in the winter weather. It is during this season that we often have some of our most severe epidemics to combat, and personal cleanliness becomes under those circumstances a powerful antagonist. We do not at this moment recall which city department has charge of the summer baths, but it seems as if all the city's free-bathing facilities might be placed with propriety under the control of the Board of Health.

The expense of maintaining such institutions would, of course, be considerable. In summer the water costs nothing. Nature furnishes that. The requirements of winter baths would necessitate steam-power for pumping and heating, and a more durable and elaborate structure. It would be possible to rent or buy large houses or unoccupied buildings in various parts of the city, in which large shallow tanks could be constructed and filled with water which could be easily steam-heated. Such buildings should be centrally placed in the tenement-house districts and kept open evenings, and possibly some hours on Sunday. Being entirely supported by public money, no private objection could be interposed against this last feature. It would be a practical illustration of the truth that cleanliness is next to godliness. The whole project would be a working illustration of preventive medicine. A warm bath, with careful clothing of the person afterward, will relieve many of the ills of exposure to cold and wet, and may break up many bodily changes which, if unchecked, would lead to acute pulmonary or other disease.

All such incentives to greater cleanliness must not be measured only by their immediate effects. They rouse aspirations after better things in other directions. An officer of one of the Bowery club-rooms for young men recently told us that one effect of membership was to lead the frequenters of the rooms to look for boarding places in better quarters than the ones with which they had formerly contented themselves, and to improve their *moral* generally. Along this line would the effect of free warm baths work itself out.

SEXUAL PERVERSION AND THE WHITECHAPEL MURDERS.

The Whitechapel murders have furnished a pretext for a large amount of medical, scientific, and ethical discussion. In particular, our Chicago confrères have betrayed interest in this subject, and their local journals and societies have been efflorescent in illustrations of sexual and moral turpitude. Dr. Reynolds has told of an "American gentleman, fifty years of age," with a passion for one-legged girls, and a Platonic indifference to his amiable and two-legged wife. This interesting specimen of the "American gentleman" could only satisfy his amatory feelings with monopedal ladies of uncertain virtue. The interesting details of this case were apparently listened to, and certainly discussed by, Dr. Fannie Dickenson, and others. Dr. Fannie asserts in her remarks that the subject brought up by the case of the "American gentleman" of fifty, "would bear much thought and action;" but along what lines we are not sufficiently or specifically informed.

Dr. Clevenger gave a demonstration of the proof, which to his mind exists, that the sexual sense is only an offshot and evolution of the sense of hunger; while Dr. Kiernan has contributed a paper on Sexual Perversion, as illustrated by the Whitechapel murders. In very much the same line as Dr. Kiernan's paper is one by Dr. E. C. Spitzka, on the Whitechapel Murders (*Journal of Nervous and Mental Diseases*). Both gentlemen concur in the view that the Whitechapel murderer was prompted to his crimes by sexual motives; and the sexual element is made the basis of much scientific and historical discussion. The occasion is used to relate some of the nasty tattle about the Cæsars, which that ancient gossip and so-called historian Suetonius has handed down to us. The story of Marshal de Raiz is told with a good many inaccuracies. For de Raiz was not the original and only Blue-beard, as is asserted, and instead of murdering nine hundred children, or one every third day for eight years, it is doubtful if the number reached one hundred—

which is quite enough, to be sure. Furthermore, the question of his murders being due to sexual motives is open to reasonable doubt, since de Raiz or de Retz had a mania for seeing Satan in person, and for making some compact by which he could obtain money and restore his wasted resources. The sacrifice of children was one of the things necessary to secure for him the personal recognition and favor of the devil.

We have digressed somewhat, simply to show that perhaps the discussions upon the Whitechapel murders have brought out the sexual element into somewhat excessive prominence, and have been, somewhat unjustifiably, made the excuse for retailing historic nastiness. The London criminal, it is said, killed only prostitutes of the lowest grade, and cut out their uterus, ovaries, and one kidney. This hardly furnishes absolute evidence of a sexual paranoiac, or, as Dr. Spitzka suggests, a degenerated sexual voluptuary. The man, indeed, showed a certain sense of moral fitness in the selection of his victims, and it might be supposed he is only a crazy reformer of personal immorality, and hopes to strike terror into the ranks of the depraved. In fact, it is quite positive that the Whitechapel murderer is a well-meaning, though excessively zealous man.

It is unfortunate that he has exercised his repressive measures on female prostitutes alone. For, if he could only pick out the corresponding class of male voluptuaries, whose soul is seated in the foreskin, and make his anatomical demonstrations upon them, his moral influence would be vastly extended.

But the Whitechapel murderer, if he is at heart a lover and reformer of his race, has taken means which society at the present time abhors, and which we trust we shall not be considered as seriously extenuating. His crimes are bad enough of themselves, and it is not necessary to add to their horror by hypotheses that are repugnant, disgusting, and as yet, not firmly substantiated by evidence.

HOW TO PRESERVE THE PHYSICIAN'S HANDS.

The question of how to disinfect the hands when a surgical operation is to be performed having been quite well settled, a problem now arises of how to preserve the hands against the assaults of modern antisepsis. The frequent washing, scrubbing, and contact with carbolic acid, corrosive sublimate, etc., sometimes ends in making the hands rough, sore, red, and unsightly. At least this is the complaint of some of our German confrères to whom, if report speaks correctly, there have not descended hereditary protective influences from ancestral scrubbings. Dr. George Meyer, of Berlin, who has been himself a sufferer from "röthen Händen," describes a method of treatment which gives great relief. After washing the hands in soap and water, and carefully drying them, the following ointment is thoroughly rubbed in:

℞. Lanolin puriss..... 100.00.
Vanillin..... 0.1.
Ol. rosar..... gt. j.
M.

The vanillin and oil of rosemary are, of course, not essential. After the application the excess is wiped off upon a towel. Small tubes, like those used by artists for holding paints can be filled with the ointment, and it is thus made easily portable.

News of the Week.

The Alumni Association of Bellevue Hospital Medical College.—The annual dinner of the Alumni Association of Bellevue Hospital Medical College was held at the Hotel Marlborough, on Saturday evening last. Dr. Lewis Hall Sayre, the President of the Association, occupied the head of the table and acted as toast-master. The following toasts were responded to: "The Clergy," by the Rev. William Lloyd; "The Alma Mater," by Professor Austin Flint; "The Alumni," by Professor Joseph D. Bryant; "The College of Physicians and Surgeons," by Dr. Frank P. Foster; "The University Medical College," by Professor Alfred L. Loomis; "The Post-Graduate Medical School," by Professor George B. Fowler; "The New York Polyclinic," by Professor Landon Carter Gray, and the "Medical Press," by Dr. George F. Shrady.

At the meeting of the Association, previous to the dinner, Dr. Lewis Hall Sayre was elected President, and Dr. A. M. Jacobus, Secretary. There was a large attendance of representative alumni, and the evening was, as usual, a very enjoyable one.

Dr. Robert Newman, of this city, in a reply to the open letter of Drs. Brewer and Otis regarding the treatment of stricture of the urethra by electrolysis, accepts the challenge, and will, in conjunction with the challengers, arrange the necessary preliminaries for an impartial test.

At the Meeting of the Trustees of the University of Pennsylvania, held last Tuesday, the following appointments were made: Dr. De Forest Willard, Clinical Professor of Orthopœdic Surgery; Dr. George A. Piersol, Professor of Histology and Embryology; and Dr. Samuel G. Dixon, Professor of Hygiene. It is stated that Mr. Henry C. Lea has given $25,000 to the Laboratory of Hygiene of the University of Pennsylvania on condition that an equal amount be obtained from other sources, and that a goodly proportion of this additional sum has been already raised.—*Medical News.*

Dr. William Read has presented the Boston Medical Library Association with his extremely valuable and rare collection of obstetric works. It comprises nearly four hundred volumes, and is thought to contain nearly everything of importance in French and English from the earliest times to 1861.

San Francisco Polyclinic.—A Polyclinic has been organized in San Francisco, and will be opened on or about March 1st. The object is charitable, medicine and advice being furnished to the sick poor gratuitously.

Ought the Doctor to Tell a Lie?—This important ethical question has been raised in the *Medical Age.* Dr. E. B. Ward, after an experience of thirty years, asserts that "a doctor is morally bound to lie under certain circumstances." Dr. W. Flagler, from an experience of five years, opposes this view and argues in favor of *suppressio veri* as a substitute for bald falsehood. By the old rule, *experientia docet,* Dr. Ward is right. But one must be careful not to confound the just conclusions of matured experience with the mental phenomena of the degenerative changes of senility. So that it seems impossible to settle the question as yet.

THE DELUGE BEGINS.—*The Southern Medical College* held its Annual Commencement on March 2d. About forty students were graduated.

At the Annual Commencement of Rush Medical College, Chicago, held on February 19th, one hundred and twenty-seven candidates were graduated. At the Commencement of the College of Physicians and Surgeons, of Chicago, held on February 26th, forty-eight candidates were graduated.

The Commencement Exercises of the Meharry Medical Department and the Dental Department of Central Tennessee College, were held on February 21st, the degree of M.D. was conferred upon fourteen, and the degree of D.D.S. upon six candidates. The Dental Department of this College is the only dental school for negroes in this country, and the Meharry school is one of the two medical schools for negroes.

The New York College of Veterinary Surgeons held its Annual Commencement on March 13th.

The University Medical College of New York held its Annual Commencement on March 12th, and graduated a class of one hundred and eighty. The graduate address was delivered by Rev. Dr. Howard Crosby. The faculty awarded the prize of $200 for the candidate whose general standing was the highest, as shown by the record of his final examination for the degree of M.D., to B. N. Bridgman. The prize of $100 to the second best, and of $50 to the third best in their final examinations, were divided evenly between J. B. Long and S. J. Keefe. The Mott medals for the best and second best anatomical or anatomico-surgical preparations, and the best book of recorded cases and remarks of the professor at either of the surgical clinics, were awarded as follows: Gold medal, John M. Cooley; silver medal, Oliver K. Isham; bronze medal, D. D. Goldstein. The prizes for hospital appointments in the competitive examinations were awarded by choice as follows: First, H. L. Constable; second, W. E. Chase; third, M. M. Rodriguez; fourth, G. C. Pope.

Bellevue Hospital Medical College Commencement.—The one hundred and thirty-eight members of the Class of '89 of Bellevue Medical College met at the Carnegie Laboratory at 6 P.M., Tuesday, March 5th, and were formally made Doctors of Medicine by President Isaac E. Taylor. It was the twenty-eighth Annual Commencement of the College. Dr. Austin Flint of the faculty read the names of the graduates, who represent nearly every State in the Union. There are also members from Cuba, Ontario, Nova Scotia, and the Dutch West Indies. Dr. F. S. Dennis, Professor of Surgery, made an address, and the class proceeded to the Hotel Brunswick, where they dined in company with the faculty and several of the Board of Trustees. Austin Flint, Jr., Frederick S. Mandelbaum, Curtis C. Morgan, and J. R. Burdett, members of the class made addresses. Dr. Lewis Hall Sayre of the faculty responded for the alumni. The four members of the class whose rank entitles them to appointment in Bellevue Hospital are—Austin Flint, Jr., George P. Biggs, George D. Stewart, and David L. Rauch. James W. Cassel and Edward P. W. Leyba are eligible for appointment to vacancies. Five graduates received honorable mention—Frederick S. Mandelbaum, Curtis C. Morgan, J. R. Burdett, John H. Douglass, and Robert S. Primrose.

THE MIND-CURE AND THE LAW.—A patient of a "clairvoyant" doctor at Madison, Wis., has sued and obtained a judgment for $1,500 (affirmed in the Supreme Court), for having been rendered a cripple through treatment for rheumatism instead of hip-joint disease, his real ailment. The court overruled the plea of the defendant that he should be free from liability because the patient was fully aware of the peculiar "school" of medicine to which he belonged.—*Medical Index.*

ANEURISM OF THE SUBCLAVIAN (*Journal de Médecine*).—Dr. Saboia has laid before the Society of Surgery notes of a case of aneurism of the subclavian treated successfully by electro-puncture. The treatment was continued fifty-five days.—*Provincial Medical Journal.*

CATHOLIC FACULTY OF MEDICINE (*Gazette Hebdomadaire des Sciences Médicales*).—It is seriously proposed to establish a Catholic Faculty of Medicine at Lyons; a subscription list has been opened, and the first list of sums promised amounts to 400,000 francs.—*Provincial Medical Journal.*

THE AMERICAN PUBLIC HEALTH ASSOCIATION is in trouble over its Lomb Prize Essay on Practical, Sanitary, and Economical Cooking for Persons of Moderate and Small Means." The Secretary, Dr. Watson, gave the manuscript to the *New York Herald* on condition that that paper published it in full. He now complains that only a garbled report was published, with sensational headlines containing such expressions as, "The Devil sends the Cook, but the *Herald* sends forth an Antidote," "Indigestion Knocked Out," "Girls, the Road to a Man's Heart is through his Stomach," "An Abel Essay," "Miss Mary Hinman Abel took the Cake." etc. Dr. Watson has doubtless learned a great deal about newspapers in the last few weeks.

A MEMBER OF THE AMERICAN PHYSIOLOGICAL SOCIETY has offered $200 for the best research or researches bearing on one or more of the subjects treated below, viz.: "The rate of transmission of nerve impulses, afferent and efferent, and the duration of reflex and reaction time in the higher animals, especially man; also the conditions, normal and pathological, which alter such rates and times." The competition is limited to residents of North America, and the prize will be awarded for original work done after January 1, 1889. Communications should be addressed to Professor H. Newell Martin, Johns Hopkins University, Baltimore, Md.

BELLEVUE HOSPITAL EXAMINATION, FOURTH DIVISION.—The competitive examination to fill vacancies on the House Staff of the Fourth Division of Bellevue Hospital, will be held at Bellevue Hospital, Tuesday, March 26th, at 2 o'clock, P.M. Written application to appear before the Examining Board, endorsed by a physician of good repute, must be sent by each candidate to the undersigned, at least one day before the date of examination.—W. F. Fluhrer, M.D., Secretary, 32 West Thirty-third Street.

DR. ALVAN TALCOTT, of Guilford, Conn., who has given $25,000 to endow a professorship of Greek at Yale College, is one of the oldest alumni of that institution. Although over eighty years old he is still a practising physician, and it is said that every night he reads a hundred lines of Homer, in the Greek, before going to sleep.

THE JOHNS HOPKINS HOSPITAL, BALTIMORE, MD.—ARRANGEMENTS FOR THE OPENING, MAY, 1889.—The Johns Hopkins Hospital will be opened to the inspection of the public, before the reception of patients, during the week beginning May 6, 1889. On Tuesday, May 7th, at 11 A.M., there will be appropriate addresses in the main administration building. Invitations to be present will be sent to the authorities of the city and State, to those who have rendered special services in promoting the plans of the hospital, to professors of medicine and surgery, to the chief managers of other hospitals, and to the representatives of the press. On Wednesday, May 8th, between the hours of 12 noon and 6 P.M., the buildings will be open to the medical profession of Baltimore, Washington, and the State of Maryland, to medical students, to the managers of the benevolent institutions of Baltimore, to the ministers of all religious denominations, and to other persons whose pursuits have led them to take a special interest in hospital work. Cards of admission will be distributed in advance. On Thursday, May 9th, and Friday, May 10th, between the hours of 12 noon and 6 P.M., the public generally will be invited to visit the hospital. Cards of admission may be obtained, on the days named, at the entrance gate of the hospital, Broadway. On Saturday, May 11th, the faculties of the various institutions in Baltimore, the teachers of public and private schools of every kind, the students of the Johns Hopkins University, the Baltimore City College, the State Normal School, the Woman's College of Baltimore, and the Eastern and Western Female High Schools, will be admitted between the hours of 10 A.M. and 6 P.M. upon the presentation of tickets which will be distributed in advance. The dispensary will be opened for the treatment of out-door patients, Monday, May 13th, at 10 A.M. The hospital will be opened soon afterward for the treatment of patients sent to it by the head of the dispensary. Persons who wish to receive treatment in the hospital at their own charge, in whole or in part, may apply, by note or through their medical adviser, to the Director or to the Chief Physician, after May 1, 1889.

DR. FRANCIS J. EVANS, of this city, died on March 11th, at the age of thirty-five years. He was born in New York, and was a graduate of the Bellevue Hospital Medical College.

DR. THOMAS J. CARROLL died at his home in this city from an overdose of morphine, on March 10th. Dr. Carroll was twenty-eight years of age. He graduated creditably from the University Medical College in 1885.

A GREEK LETTER MEDICAL SOCIETY, the Delta Epsilon Iota, has been organized by the students of the Yale Medical College.

THE NEWPORT MEETING OF THE AMERICAN MEDICAL ASSOCIATION will at least be likely to be free from any local strifes and jealousies, for every one of the regular practitioners in town (fifteen in all), has a place on the local committee of arrangements, while three more of the committee are dentists. The local secretary first appointed having resigned, Dr. Valentine Mott Francis has taken his place. Dr. Horatio R. Storer, Chairman of the Committee of Arrangements, says: "The meeting of the Association occurs nearly synchronously with the two hundred and fiftieth anniversary of the settlement of Newport. The city authorities will probably fittingly recognize the presence of the National Medical Convention at such a moment, the more cordially since the virtual founder of the colony, certainly its principal leader, John Clark, was a physician. It will add to the interest of the occasion that the now mayor of the city was one of the incorporators, in 1879, of the Newport Sanitary Protection Association, and is the parent of a rapidly rising physician in New York. The ancient name of Newport Island was 'Aquidneck,' or 'The Isle of Peace.' In view of this, it is to be hoped that the wisdom of the Association in turning away, the present year, from the mutual rivalries and the internal dissensions inseparable from the great centres of practice and of medical education, to what is virtually neutral ground, may be made manifest, and that the coming session may prove one of the largest, most harmonious, most scientific, and best contented meetings that has yet been held."

NEW INSANE ASYLUMS.—California is to have a new insane asylum in the southern part of the State, and a new branch asylum at Ukiah.

ANOTHER CASE OF DEATH FROM "CHRISTIAN SCIENCE" is reported at Pierre, Dak.

A PROFESSIONAL CARD.—The following is said, by the *Medical and Surgical Reporter*, to be clipped from an Arizona weekly of respectability:

"J. E. ——, M.D.,

PHYSICIAN AND SURGEON.

Health Officer, City of ——; for five years County Physician —— County; Medical Director Department of Arizona, G. A. R.; Late Surgeon U. S. Army; for 20 years U. S. Examining Surgeon; the largest Medical Practitioner in Arizona, and charges fees in proportion to his size. His patrons will find it to their advantage to keep healthy.

Office and Dispensary, - - —— Street,

Corner of ——,

——, - - - ARIZONA.

"THE MARITIME MEDICAL NEWS" is the title of a new journal published bi-monthly at Halifax, N. S. The appearance of its first two numbers is very creditable and gives promise that the journal has before it a long and useful existence.

A BILL TO REGULATE THE PRACTICE OF MEDICINE IN MICHIGAN has been introduced into the Legislature. It provides for the appointment by the Governor of a board of six physicians to be medical examiners. Two are to be of the homœopathic school, two eclectics, and two regulars. All are to be graduates, but none can be connected with a medical college in any capacity. Any person practising medicine without a license from this board may be fined $100 or sentenced to jail for ninety days. All persons are regarded as practising who append M.D. or M.B. to their names, or direct, or for a fee recom-

mend for the medicinal use of any person any drug. Every person licensed must have attended three courses of lectures of at least six months each, and must be examined in the fourteen standard branches of medical practice. The examination fee is $10, and the license must be filed with the county clerk. The board can revoke a license for unprofessional or immoral conduct.—*Medical Standard.*

PAY FOR EXPERT TESTIMONY.—Dr. G. K. Johnson, of Grand Rapids, has declined to testify before a United States pension examiner without compensation, and the question is to be settled in the courts.—*Medical Standard.*

Reviews and Notices of Books.

THE EAR AND ITS DISEASES: Being Practical Contributions to the Study of Otology. By SAMUEL SEXTON, M.D., Aural Surgeon to the New York Eye and Ear Infirmary; Fellow of the American Otological Society; Member of the Practitioners' Society of New York, etc. Edited by CHRISTOPHER J. COLLES, M.D., Assistant Aural Surgeon to the New York Eye and Ear Infirmary. 8vo, pp. 461. New York: William Wood & Co. 1888.

THE contents of this work are divided into four parts: Part I., of 60 pages, describes the Anatomy and Physiology of the Auricle, External Auditory Canal and Contiguous Parts, and the Membrana Tympani. Part II., of 50 pages, is devoted to the Etiology of Aural Diseases. Part III., of nearly 300 pages, gives the author's views on Wounds, Injuries, and Diseases of the Ear, and their Treatment. Part IV., of 50 pages, contains several Miscellaneous Articles, in connection with whose topics the author's name is, perhaps, most familiar to the general medical reader. Some of these are as follows: The Education of School Children with Defective Hearing, and the Extent of Deafness in the Schools; The Effect of High Atmospheric Pressure on the Ear in Tunnels, Caissons, etc.; The Effect of Submarine Diving on the Ear; Claims of Soldiers, Sailors, and Marines for Pensions on Account of Disability from Deafness.

The entire field of otology is not attempted in this admirable book, but such subjects have been embraced as will prove of general interest to the profession. The records of 10,000 aural cases, or about one-third of all such as have fallen to the author's practice in the last twenty years are made the basis of the work. The chapter on wounds and injuries of the ear is the most complete of any yet written, particularly those occurring in warfare, and are based on the author's own experience; an invaluable feature for reference for Army, Navy, and Pension Surgeons.

Chapter VI., on Catarrh of the Upper Air-tracts, and Chapter VII., on Oral Irritation as a Reflex Cause of Aural Disease, will bear careful and critical reading. From carefully recorded observations of some 1,800 cases of aural disease associated with severe dental irritation, the author finds 93 cases of acute, 33 of subacute, and 638 of chronic catarrhal inflammation of the middle ear; 235 cases of acute, 4 of subacute, and 401 of chronic purulent inflammation of the middle ear; there were 26 cases of severe purulent otitis, involving the mastoid cellules. The attempt to preserve very defective teeth, especially in run-down persons, is strongly advised against.

In impending periostitis externa and interna the author takes middle ground between the advocates of severe surgical measures and those who rely upon constitutional means of treatment; on the one hand he inveighs against the indiscriminate use of the leech and Wilde's incision into the mastoid periosteum, while on the other hand he finds from long experience that calx sulphurata holds its own in otitis media acuta non-suppurativa, as also in otitis suppurativa (perforans). The author calls attention to the relief that may immediately follow an incision into the attic in painful inflammation of the middle-ear, which is so common in childhood.

The medical profession will be under a lasting obligation to Dr. Sexton for his chapter of forty pages on the Operation of Excision of the Drumhead and Ossicles. Sir Astley Cooper once expressed the hope that deafness might be relieved by an operation having for its purpose the admission of sound through the round and oval windows, connecting the tympanic cavity and labyrinth, by means of a permanent opening in the drumhead. The operations of Heinly, Fabrizi, Brunner, Deleau, and Bonnafont did not prevent the opening into the drum-head from closing over by a secondary membrane. Wreden excised the manubrium mallei; Schwartze excised the malleus and incus in 1873, and neither of these operators succeeded as they expected; in 1878 Kessel, of Gratz, removed the drum-head, malleus, and incus in a case of chronic catarrh of the middle ear with closure of the Eustachian tube; the hearing-distance before the excision was ten centimetres, and tinnitus was very great. The final hearing-distance was ten metres, and tinnitus was slight. In 1881 Lucæ, of Berlin, detailed 25 cases of excision of drum-head and malleus, in none of which was there deterioration of hearing, and in many great improvement of aural power. In 1885 Lucæ had performed 53 operations of excision of drumhead and malleus, in 6 of which the incus was also removed. Since his first operation in 1886, with his own special instruments, the author has made over 40 excisions of drum-head, malleus, and incus, of 36 of which the details are given with painstaking accuracy. Over fifty per cent. of these cases were cured, while of the remainder all were improved, the degree of improvement being variable. Reproduction of the drum-head took place in none of the cases; and in none was there a recurrence of otorrhœa, or otalgia, or other distressing acoustic phenomena. The author believes that many deaf-mutes could be restored to hearing by this operation. It should be stated that slight swelling of the auditory canal, hemorrhage, and some pain may exceptionally be expected to succeed the operation, but that the excision is free from danger when ordinary precaution is observed. It is best undertaken under narcosis, and usually occupies ten to fifteen minutes after this is established. On the whole, Dr. Sexton has offered a book of definite character to the general medical reader of otological literature, while it cannot fail, by its advanced teaching, to be of interest to the otologist.

DIE ENTWICKLUNG DER BAKTERIENFÄRBUNG. Eine historisch-kritische Uebersicht. Von P. G. UNNA Jena: Gustav Fischer. 1888.

IN this brochure the author treats quite exhaustively of the history of staining methods for bacteria, and of the gradual development, during the first few years, of this process, so indispensable in bacteriological investigations. The history is an interesting one to all who watch the onward progress of scientific study in our day.

THE ELECTRIC ILLUMINATION OF THE BLADDER AND URETHRA AS A MEANS OF DIAGNOSIS OF OBSCURE VÆSICO-URETHRAL DISEASES. By E. MURRY FENWICK, F.R.C.S. London: J. A. Churchill. 1888.

THIS work is the substance of two lectures delivered at the London Hospital and St. Peter's Hospital for urinary diseases. The author lays stress on improvements in the Nitze-Leiter method, and after giving a detailed description of the instrument itself, predicts its further development and universal use. The literature is entirely new, as, with the exception of Nitze's article, nothing has been written on this subject. It is profusely illustrated with wood-cuts.

Society Reports.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 26, 1888.

W. P. NORTHRUP, M.D., PRESIDENT, IN THE CHAIR.

DR. JOHN S. ELY presented a monstrosity of the type

MICROMELUS.

There was no history of the parents of the child. The trunk and head were apparently well formed, but the arms and legs were almost rudimentary as regarded their length, although in thickness they were nearly normal. The bones of the arm and forearm were present, and the hands, though small, were not especially misshapen, nor were the fingers webbed. In the lower extremities the femur was very short and much curved. Both bones of the leg were apparently present, although it was difficult to assure one's self of this by reason of the small size of the member. The great toe stood out at nearly a right angle with the inner border of the foot, and the feet were inverted so that the soles nearly opposed each other. The appearance of the feet and great toes suggested the normal condition existing in apes.

DR. L. EMMETT HOLT showed a series of specimens illustrating enlarged cheesy bronchial glands. The first specimen was one of

GENERAL TUBERCULOSIS, ENLARGED BRONCHIAL GLANDS, WITH ULCERATION INTO THE RIGHT BRONCHUS.

Female child, seven months old; family history unknown; three months before death she had an attack which was diagnosticated pleurisy, from which she never fully recovered. Had constant cough and considerable mucopurulent expectoration. There were continuous febrile symptoms for one month before death; the temperature range was between 101° and 104°, having the peculiarity that it was almost always higher in the morning than in the evening. There was progressive emaciation, moderate diarrhœa, no marked cerebral symptoms. There was much purulent expectoration. The physical signs gradually extended until there were signs of consolidation throughout the greater part of the right lung, in front and laterally, and scattered areas behind. Close to the spine, in the right interscapular region, there was a circumscribed area of marked dulness. The respiration here was exaggerated bronchial. Both were in striking contrast to the signs on the left side of the spine, and were interpreted to mean enlarged bronchial glands upon the right side. In the left lung there were no evidences of consolidation, but of a generalized bronchitis of the smaller tubes.

Autopsy, fourteen hours after death.—Brain: A few miliary tubercles were present, and a very slight amount of meningitis, chiefly over the right parietal lobe.

Chest—Right Lung: Upper lobe firmly adherent, and tears on removal. On section it shows many cheesy areas broken down in the centre, forming small cavities from one-eighth to one-half inch in diameter. One larger cavity near the anterior border filled with pus. The middle and lower lobes show many cheesy nodules, mostly smaller than in upper lobe. The intervening lung-tissue is in places consolidated and filled with miliary tubercles. Left lung: No adhesions; both lobes studded with small cheesy nodules, the longest being one-quarter inch in diameter, the intervening tissue being normal. Bronchial glands: They form a large mass above the right bronchus, the largest ones being nearly one inch in diameter; they are fused together. An ulceration exists in the right bronchus half an inch from the bifurcation of the trachea, which includes half the circumference of the bronchial wall. It communicates with a broken-down gland outside. Heart and pericardium normal.

Abdomen: The spleen was much enlarged (weight, seven ounces) and contained miliary tubefcles. Many tubercles were found in the liver, also enlarged, and a few in the kidneys. The small intestine was healthy, except the ileum, which contained small tubercular ulcers in almost every Peyer's patch, and a very few elsewhere. The large intestine showed slight catarrhal changes only. Mesentric glands cheesy, the largest being half an inch in diameter. Stomach pale, otherwise normal.

A second specimen showed

GENERAL TUBERCULOSIS, TUBERCULAR MENINGITIS, CEREBRAL THROMBOSIS AND SOFTENING; ENLARGED BRONCHIAL GLANDS, WITH ULCERATION INTO THE RIGHT BRONCHUS.

Male, seven months old; family markedly tubercular upon the father's side; in fair condition until two months before death, when pertussis developed; attack rather more than average severity. Lost weight steadily, but had no other noteworthy symptoms till twelve days before death. His temperature was not high, only once touching 103°. A week before death the first signs of consolidation were found in the lungs; they were in the right upper lobe. Subsequently these signs were heard over the lower lobe and on the left side near the spine. At the last examination of the chest a circumscribed area of dulness was found in the right interscapular region. This was not accompanied by the peculiar respiration noted in the previous case, but by ordinary bronchial breathing rather louder than usual. The diagnosis of enlarged bronchial glands was made, although no dulness was found on the upper part of the sternum. The spleen was easily felt below the ribs. Cerebral symptoms were present during the last week; first drowsiness, the next day opisthotonos and an attack of convulsions, and later, complete coma; pupils dilated, responding sluggishly; slight convergent strabismus; paralysis of the lower half of the right face; right arm and leg rigid; knee-jerk normal, or slightly increased; rapid pulse, and Cheyne-Stokes respiration. Convulsive twitchings were present during the last six hours. Death occurred quietly.

Autopsy, sixty hours after death.—Brain: Extensive basilar meningitis, more marked in the left Sylvian fissure. Lobes matted together by lymph, and pia studded with miliary tubercles. A few tubercles over the convexity. A firm thrombus in the left middle cerebral artery, not decolorized; a spot of red softening in the central portion of the frontal lobe, nearly as large as hen's egg; ventricles moderately distended with clear serum.

Cord not examined.

Chest—Right lung: Old adhesion over middle lobe quite firm, slight recent adhesions over lower lobe. Upper lobe shows a few miliary tubercles on its surface, and small cheesy nodules in the interior; middle lobe completely broken in its centre, forming a series of small cavities, filled with cheesy material and some fluid pus; lower lobe consolidated from broncho-pneumonia, with here and there minute cheesy spots at the lower portion. Left lung: A few miliary tubercles on the surface; on section, several small areas of broncho-pneumonia, and two or three broken-down cheesy nodules near the root. Bronchial glands: Very much enlarged on the right side, forming a mass two inches long and three-fourths of an inch wide. They are all cheesy, and some are broken down. There was an ulceration into the right bronchus, occupying exactly the site described in the previous case, viz., half an inch from the bifurcation of the trachea. This was nearly one-fourth of an inch in diameter. Glands on the left side were slightly swollen, but not cheesy. Heart and pericardium normal.

Abdomen: Spleen much enlarged, fully four times the normal size, filled with miliary tubercles, and many small cheesy nodules. Liver pale, tubercles on surface, and a few in its substance. Kidneys: A few tubercles on the surface; quite marked; cloudy swelling of cortex. Stomach normal. Small intestine normal, except ileum; Peyer's patches swollen and red, and nearly every one contains one or two small, circular tubercular ulcers. Large intes-

tine: Half-a-dozen small ulcers scattered through the colon. Mesenteric glands moderately enlarged and cheesy.

A third specimen illustrated

GENERAL TUBERCULOSIS; PERSISTENT OPISTHOTONOS, WITHOUT LESION OF BRAIN OR CORD.

Male child, aged seven months, always delicate; family history unknown. Weighed eight pounds on admission in July, being then two months old. During the next three months gained two pounds, and then gradually lost it. Emaciating slowly till death. In October attention was called to the child by reason of opisthotonos, which had then existed some weeks. The neck was so rigid that the body could be raised by the head. This continued with slight variation, but never being completely absent until death. An irregular fever began early in October, which lasted six weeks, the temperature ranging from 100° to 103° F. Careful and repeated examinations were made during this period, eliciting only a moderate enlargement of the spleen and the signs of general bronchitis over the chest, mainly of the larger tubes. There were no cerebral symptoms. Quinine was without avail. Moderate gastro-intestinal catarrh was present, but hardly enough to explain the symptoms.

In spite of numerous changes in diet, and finally wet-nursing, he lost ground steadily. Toward the last he had no fever, but little cough, and the opisthotonos, although present, was not so marked as in October. At the last recorded examination of the chest, two or three weeks before death, the only signs present were scattered coarse râles. He died of exhaustion December 18th, wasted to a skeleton.

Autopsy, ten hours after death.—Brain and cord absolutely normal; they were examined with great care. Lungs: Left, quite large areas of consolidation in both lobes, chiefly posteriorly; on section, many cheesy nodules and a few quite large areas infiltrated with cheesy products. Right lung, small cheesy nodules scattered through the whole lung; many miliary tubercles on the surface; very little pneumonia. Bronchial glands are all enlarged and cheesy. They form a large mass surrounding the trachea and bronchi, but lie chiefly in front. Most of the glands are the size of a hazel-nut, and are beginning to break down. Heart and pericardium normal. Spleen about twice the usual size; many small cheesy nodules and miliary tubercles. Liver congested; a few miliary tubercles. Kidneys: Quite marked cloudy swelling; no tubercles. Intestines: A few small, circular ulcers in the lower ileum, and about a dozen scattered through the colon; moderate catarrhal changes through lower ileum and colon. Mesenteric glands size of a small marble, and cheesy. Stomach small, but mucous membrane normal.

Remarks.—In the first case the ulceration of the bronchus was probably produced by the breaking down of the gland exterior to it. The distribution of the inflammatory products suggested that this opening had existed for some time, and that the lesions in the middle and lower lobes had been set up by the aspiration of cheesy matter from the gland which had been discharged into the bronchus. The appearance in the left lung indicated this still more strongly; the matter having been coughed up into the trachea and then aspirated into the lung.

In the second case no cheesy gland existed near the opening into the bronchus, and this perforation was probably due to tubercular infiltration of the bronchial wall which had broken down.

In the third case the absence of all evidence of basilar meningitis at the autopsy was, in view of the persistent opisthotonos, rather surprising. The only explanation of the symptom which appeared was that it might have been reflex from irritation of some of the peripheral filaments of the spinal accessory by the tubercular gland which extended some distance into the neck.

DR. HOLT presented some additional specimens showing

DIPHTHERIA; MEMBRANE IN THE LARYNX, WITH NO CROUPY SYMPTOMS DURING LIFE; BRONCHO-PNEUMONIA.

A stout male child, aged sixteen months, was taken sick six days before death with high fever and sore throat. The temperature for the first twenty-four hours was 104° F.; during the next thirty-six hours it was low, ranging from 100° to 101° F.; during the last three days it ranged from 103° to 105° F. In the beginning both tonsils were swollen and congested, and a patch was seen upon the left. The next day one was noticed upon the right side also. There were no nasal symptoms and but moderate swelling of the cervical glands. The membrane in the throat did not spread beyond the tonsils. With the second rise of temperature the signs and symptoms of severe broncho-pneumonia developed which caused death. Throughout the attack there was no stupor, no laryngeal dyspnœa, and only slight hoarseness. Croup was not suspected.

Autopsy, twenty hours after death—Brain normal. Larynx: Epiglottis much swollen, especially at its borders, and is folded laterally upon itself. It is entirely covered with a thick adherent false membrane, excepting its base anteriorly. Thick membrane also covers the aryteno-epiglottidean folds. These are also swollen. The interior of the larynx is lined everywhere by a thin false membrane which extends into the trachea nearly an inch. It is very loosely attached in the trachea, but quite firmly so in the larynx. There was moderate congestion and swelling of the mucous membrane of the trachea and larger bronchi, but no more false membrane encountered until the third or fourth divisions of the bronchi were reached. Here the membrane was abundant, but loosely attached; it could be drawn out of the small bronchi in pieces of considerable length. This was present only in the bronchi of the right lung, none could be seen upon the left side.

Both lungs showed extensive broncho-pneumonia; nearly the whole lower lobe and the posterior part of the upper lobe being involved on the right side, and quite a wide strip along the posterior border of both lobes upon the left side. The lungs were everywhere much congested. The heart showed quite large decolorized clots in both auricles and ventricles, larger upon the right side; they were but slightly adherent and probably post mortem. In the kidneys there was well-marked cloudy swelling of the cortex.

The other organs were substantially normal.

THE PRESIDENT did not think that ulceration from the presence of enlarged glands was of very common occurrence. Referring to the case in which opisthotonos was present, he said that the causation of this symptom in young children was a subject of considerable interest. He had seen it in "marasmus babies" in which there was no brain or cord lesion discoverable post mortem. The only lesion constantly present, in the three or four cases which had come under his observation was gastro-enteritis. It was interesting also to note the occasional absence of symptoms in cases of glottic stenosis. He had that day removed from the body of a child a larynx in which there was a considerable amount of false membrane, as thick as blotting-paper, lining the opening in the larynx, and yet there had been no symptoms whatever of stenosis.

DR. JOHN C. PETERS said that to this Society belonged the credit of first establishing the diagnosis of diphtheria as a distinct disease in this country. A number of specimens had been presented here during the years 1842, 1843, and 1844.

DR. WILLIAM P. NORTHRUP presented some microscope slides of sections of specimens from three cases of

ACTINOMYCOSIS IN MAN.

Two of them were from two of the three cases operated on by Dr. Frederick Lange, of this city, and one was a specimen from Heidelberg. The ray fungus was well shown in one teazed unstained specimen, and differently represented by a hardened section, doubly stained, in a second.

One was from a boy, from Pennsylvania, without history showing source of infection. The tumors were in the mediastinum.

The second was from a butcher of this city, who asked if his disease was like the "little pearls" seen in the lower jaw of cattle. The tumor, from which the sections had been prepared, lay at the side of the thyroid cartilage, and was about the size of a horse-chestnut. It communicated with the jaw and a carious tooth by a sinus, along which were scattered small, yellow, seedlike bodies, having the size and general appearance of miliary tubercules.

The infection entered through the cavity of the carious tooth, and advanced to the region afterward indicated by the tumor. Whether there were other similar tumors within the thorax, in the posterior mediastinum, was not indicated by symptoms at the time of operation.

The specimen was presented through the courtesy of Dr. Lange as a "card specimen," and will be fully recorded elsewhere.

The Society then went into executive session.

Anniversary Meeting, January 9, 1889.

WILLIAM P. NORTHRUP, M.D., PRESIDENT, IN THE CHAIR.

DR. E. C. SPITZKA presented

A MONSTROSITY ATTRIBUTED TO A MATERNAL IMPRESSION.

The specimen was sent to him for examination by Dr. William P. Lowman, of Orangeburg, S. C., who had been called to attend a colored woman, with the following history. When she was about two months advanced in pregnancy, while passing through some woods, she suddenly came upon a buzzard, who, having caught a pig, had devoured the greater part of its head. She was greatly startled, and was almost immediately attacked with uneasy sensations in the hypogastrium. Two weeks later these culminated in violent parturient pains. The doctor was called in at this juncture and learned the above facts. He diagnosed incipient miscarriage, which he succeeded in preventing. One month (twenty-eight days) after this severe pains set in again, and the contents of the uterus were expelled. Fortunately Dr. Lowman was called in, and his careful examination led to the discovery of a remarkable body, which on first sight struck him as resembling the body of a bird, about the size of a robin, but lacking the head. Even the skin resembled that of a plucked bird. The umbilical cord was normally attached, and the placenta—about two and one-half centimetres in diameter—also appeared normal. The feet presented a spread claw-like appearance, imitating a bird's foot even to the subsidiary posterior digit with its long claw.

The monstrosity was in every respect a maldeveloped human fœtus. The shape of the bones where exposed, the formation of the ribs, the minute characters of the articulations, and the disposition of the fœtal membranes, all left no doubt upon this head. Nevertheless, the surface resemblance to a decapitated and plucked bird was very great. The skin everywhere, except at the points of the extremities, presented the "goose-skin" appearance. The neck was long, bent over, ventro-lateral, and its terminal tissues appeared to be rounded off smoothly. The upper extremities terminated at the distal humeral end, which was covered by a membrane continuous with the subcutaneous tissues. The disposition of the thighs and legs was marvellously bird-like, particularly in the contour of the muscular masses. The feet were human feet, exhibiting a tendency to syndactylism; but on the left foot was a claw, set back as in the bird's foot. The back of the monstrosity was prolonged into a caudal extremity very similar to what is seen in a bird. The rudimentary anterior extremities were so applied against the sides as to require no great stretch of the imagination to see in them the wing-bones. The chest also resembled almost exactly that of a robin.

Dr. Spitzka remarked that this case fulfilled one of the conditions demanded by the disbelievers in maternal impressions, namely, that the woman should have related her impression before the delivery of the fœtus. An interesting speculation might be indulged in regarding the unconscious psychological process and impression, which combined the impression of the *bird*, which had its head, with the *headless* character of the pig. It may be also questioned whether the—to a woman—familiar figure of a plucked bird was superadded. The case, the speaker said, offered a valuable and unimpeachable record of a maternal impression.

DR. WALTER MENDELSON said that what struck him as very singular was that the monstrosity did not resemble the large bird that the woman had seen. Might the occurrence not be explained by assuming that the woman's mind was dwelling simply upon the appearance of a bird, and her thoughts then unconsciously took the direction of what was most familiar to her, the dressed barn-yard fowl?

DR. SPITZKA agreed with Dr. Mendelson in this explanation. It would be impossible, he said, for a maternal impression to produce a being of a different order, such as a bird with a beak or with feathers. In reply to a question, he said that he did not know how maternal impressions acted. But the cumulative evidence in support of the opinion that they were efficient factors in the production of monstrosities, in certain cases, was too strong to be gainsaid. It is not a valid argument against a fact to say that we do not know how it is produced. We see actual lesions occurring in hysterical patients as a result of purely psychological causes, yet we cannot trace the mechanism of their production.

DR. FREEMAN presented the arm of an infant, four months old showing

ABSENCE OF THE RADIUS.

The first metacarpal bone and thumb were also wanting. Cases such as this, the speaker said, are not very rare, some thirty-five or forty having been reported. The history of the child's parents was unknown, and no cause for the deformity could be ascertained.

DR. JOHN S. ELY presented a heart showing the lesions of

MALIGNANT ENDOCARDITIS,

in which the source of infection was probably a urethritis, with the history and remarks given on page 287.

DR. W. P. NORTHRUP presented some specimens illustrating

HEMORRHAGE INTO THE SUPRARENAL BODIES, WITH DISCOLORATION OF THE SKIN,

incomplete septum ventriculorum, and sprue. A female child was admitted to the New York Foundling Asylum when one day old and was entered upon the books: "Condition poor—conjunctivitis—occasional cyanosis." There was a superficial ulcer over the soft palate extending upon the hard, which on the following day was pronounced diphtheritic. Two days before death the temperature reached 103° F., and dulness developed over the left lung, behind. A distinct exudate was seen upon the tonsils. The child died suddenly, on the eighth day of life, of heart failure, thought to be due to diphtheritic poison. Beyond occasional cyanosis there is no further note of its color during life. On autopsy the body was fairly nourished, the skin and subcutaneous tissue having a yellowish-brown or dirty yellow color; skin slightly mottled. The color was distinct and not to be overlooked. The trachea and bronchi contained a moderate amount of tenacious, dirty, frothy mucus; the mucous membrane was not congested and there was no exudate upon its surface. Upon the walls of the pharynx, the soft palate, and extending down the entire œsophagus, was an abundant growth of sprue or thrush (which had been called diphtheria during life). There was no ulceration, and the pellicle differed from the fibrinous exudate by appearing coarsely granular. This was best seen upon the œsophagus of the specimen. The stomach contained an in-

creased amount of tenacious, dirty mucus and gave no evidence of the presence of any vegetable growth. The jejunum and ileum contained dark-greenish masses of mucus in a dirty, frothy fluid. Follicles were not swollen. The bronchial glands were slightly enlarged. Left pleural cavity contained about ʒ jss. of a dirty brown fluid, in which were shreds of fibrin. The visceral pleura of the lower two-thirds was fringed with fibrin and overlay a densely solidified lung. Of the right lung but a small portion of the lower posterior portion wasaffected by congestion. The pleura and pericardium contained a small amount of dirty brown fluid.

INCOMPLETE SEPTUM VENTRICULORUM.

There was a direct communication between the ventricles of the heart, by an opening at the attachment of the aorta, to the left base and the valve-attachment of the right tricuspid.

The communication was through an interval left in the development of the fibrous auriculo-ventricular bands. The opening was circular, 6 mm. in diameter, looking into the left ventricle at the attachment of the aorta to the ventricle, its upper convex margin interdigitating with the lower convex attachments of two semilunar valves.

It looked into the right ventricle, having, upon its left, the inner portion of the ventricular wall, which was at this point prolonged into the infundibulum or conus arteriosus. Above and to the left it had the ventricle muscle. It had below and to the right the fibrous attachments of the tricuspid valves, opening behind the cusp, which had its attachment nearest the pulmonary orifice.

During systole, then, the tricuspid valves being closed, the blood would tend to escape behind the cusp, through the opening, in the manner of the coronary circulation behind the aortic valves. On the other hand, the contraction of the left ventricle would tend to equalize or overcome this pressure, until some peripheral embarrassment in circulation should disturb the equilibrium, when cyanosis would appear. Of such temporary disturbance the history makes mention. The foramen ovale was patent, in its posterior portion, about the normal degree. Ductus arteriosus was also pervious.

Kidneys were congested and contained urates in the papillæ which radiated from apex to base in reddish, fine lines. The suprarenal gland of the right side was increased in thickness, its middle third being dark and congested. The left gland was three centimetres long by rather more than one in thickness, pyriform in shape. The color was mostly opaque white, bordered on one side of its greatest enlargement by an irregular zone of recent hemorrhage. The gross appearance was that of cheesy degeneration of tubercle. Microscopic examination showed a small amount of normal gland-tissue in the smaller end of the pear-shaped body, a large mass in the middle of broken-down tissue in degeneration giving the opaque white color already referred to; beyond this there were signs of recent hemorrhage. In the midst of the broken-down tissue was a large vessel containing a thrombus. There was no tubercle tissue; the destruction of the gland was due to hemorrhage. In the congested middle zone of the right gland were numerous bilirubin crystals which showed distinctly in the specimen presented.

The anatomical diagnosis of the case is twofold. First, it is apoplexy of one suprarenal body and pigmented skin, in a child of eight days. It is not considered a case of Addison's disease. Apoplexy of the suprarenals is not among children regarded as rare by writers. Congestion and discoloration of the medullary substance is common, but, in Dr. Northrup's experience, apoplexy, with destruction of tissue and enlargement of the body, can be said to be rare. Second, the case is one of sprue or thrush, which was diagnosticated diphtheria, and malformation of the heart, with sudden death. There were patches on the tonsils and palate, which appeared to be pseudo-membrane to a man eminently capable of judging; and when the child died, suddenly, it was thought to be heart failure after diphtheria.

The microscope showed the fine, granular, grayish pellicle to be oidium albicans, growing upon the surface of the mucous membrane.

DR. L. EMMETT HOLT said that he had recently come across the statement that oidium albicans was not the fungus concerned in the formation of sprue, but that it was saccharomyces albicans, and he asked whether this was a fact, which had been affirmed also by others.

DR. MENDELSON said that when in Leipsic, in 1882, he remembered having heard the statement that the sprue fungus was not oidium albicans, but a mycoderma.

DR. HOLT asked whether Dr. Northrup had ever noted the presence of the thrush fungus in the intestinal canal.

DR. NORTHRUP replied that he had never seen it below the œsophagus.

The Society then went into executive session.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE HUNTERIAN ORATION AT THE COLLEGE OF SURGEONS —THE STRUGGLE FOR POWER AT THE COLLEGE—THE PROPER PERIOD FOR SURGICAL INTERFERENCE IN CASES OF ACUTE INTESTINAL OBSTRUCTION—A CASE OF EPILEPSY WITH OLFACTORY AURA—A CHAIR OF NEUROPATHOLOGY AT KING'S COLLEGE.

LONDON, February 23, 1889.

THE annual Hunterian Oration at the College of Surgeons was delivered last week by Mr. Henry Power. So many Hunterian orators have preceded him that Mr. Power might be excused had he delivered a very mediocre and dry address. He managed on the contrary to impart a little fresh life to the subject, and that, not by departing from it to discuss other topics, but by adhering almost strictly to his theme throughout. In these days of high-pressure education it is very salutary to be reminded that John Hunter did not begin his professional studies till he was nearly thirty years of age, but that his student career was prolonged for nearly eight years. Yet the facts he had to learn in anatomy and physiology, said Mr. Power, were comparatively few, while surgery was chiefly taught in a practical fashion. Hunter began life when the disposition to recur to experiment for the solution of difficult questions in physics and chemistry was familiar to all scientific men. Many qualities must be combined to make a good experimenter, and it was pointed out by the orator how these were united in Hunter.

One phrase in Mr. Power's oration—that if Hunter were now to return to life he would see vast improvements on all sides and find a profession fairly united—recalls another topic in connection with the College, viz., the protracted struggle between the Council and the Fellows and Members. During the last few days another step has been taken which must further embitter the quarrel. Finding that the Council of the College would not summon a meeting of Fellows and Members at the College, although requisitioned to do so, the Association of Members have taken the risk of summoning one on their own responsibility. The result of this is, firstly, that they have been informed by the Council that such a meeting is illegal and contrary to the by-laws, and will not be permitted, and, secondly, that the Council have taken effectual means to prevent the meeting from being held at the College by unanimously resolving to close the College on the day for which the meeting was summoned, viz., Thursday next. And so the controversy goes on.

What is the proper period for surgical interference in cases of acute intestinal obstruction? Dr. Richardson

thinks that an exploratory incision into the abdomen should be made when fæcal vomiting comes on. This, at any rate, is the view he put before the Fellows of the Medical Society of London, in a paper read at their last meeting. After narrating a fatal case of acute obstruction which had occurred in his own practice, he discussed the question of early operative interference. Milder measures, such as purgatives, enemata, massage, etc., might, he thought, be safely carried out until the supervention of fæcal vomiting. In the presence of this symptom, however, obscurity of diagnosis ought not to be allowed to stand in the way of an operation. Clinical experience showed that there was little chance of recovery when once stercoraceous vomiting had set in, and he maintained that it was a symptom of much greater gravity than would attach to the mere mechanical effect of obstruction. Symptoms of collapse did not contra-indicate operative interference. The test proposed by Dr. Richardson did not meet with a very ready acceptance from the Society, judging by the utterances of those who discussed it. Mr. Edmund Owen remarked that the test was not applicable to a large class of cases in which the obstruction was high up, say in the jejunum. In such cases fæcal vomiting could not take place, and if they allowed the patient to go on while they waited for it, the patient's chances of recovery would be few. Mr. Bryant urged that in any case much valuable time would be lost by waiting for fæcal vomiting to come on; the surgeon should be prepared to operate directly he was satisfied there were symptoms of strangulation. Dr. Routh took up the opposite view and argued against too early operation. He had seen many cases recover without operation, although stercoraceous vomiting had occurred. He recommended a freer use of antispasmodics, such as chloroform and belladonna. Dr. Richardson, in reply, acknowledged that he had not mentioned the cases of obstruction high up, but such cases were very rare. His conviction was that fæcal vomiting was generally the first sign to impress the practitioner in attendance with a sense of the gravity of the case. If they trusted in the measures suggested by Dr. Routh, patients would often die. He admitted the value of belladonna and other drugs, however, in cases of gall-stone colic—a subject which he had not discussed in his paper.

At the same meeting of the Society, Dr. Hughlings Jackson and Dr. Beevor read notes of a case of epilepsy with olfactory aura. There was no anosmia, but only a disordered subjective sensation, viz., a horridly nauseous smell. Post-mortem, a small round-celled sarcoma was found occupying the anterior end of the temporo-sphenoidal lobe. Dr. Jackson observed that this was the first case on record in which this variety of epilepsy had been proved at the necropsy to be associated with actual lesion in the temporo-sphenoidal region.

A professorship of Neuro-pathology has been created at King's College, and Dr. Ferrier, who has resigned the chair of Forensic Medicine, has been appointed to it. King's College is evidently determined not to be behind its rivals. The present is the third additional professorship which has been instituted within the last few years. The previous two were those of Clinical Therapeutics, to which Dr. Burney Yeo was appointed, and of Bacteriology —the latter being now held by Professor Crookshank.

DR. ALONZO CLARK AND MICROSCOPY; A REMINISCENCE BY ONE OF HIS CLASSMATES.

To the Editor of The Medical Record.

SIR: In The Medical Record of February 23, 1889, is an article which discusses the question as to who introduced the use of the microscope for the diagnosis of the different diseases of the human body. I cannot tell you anything that will be of value, but as we lived near together on the Green Mountain Berkshire hills of Massachusetts, and were in college together, I will make a short statement.

When I entered Williams College, in September, 1827, Alonzo Clark was in the senior class and criticised my first college composition. He graduated in September, 1828. When he left college he was said to be engaged to a Miss Sloan, a fine young lady of Williamstown, but she lived but a short time after he left college. I never knew of his being engaged to any other lady.

He was engaged in teaching some time after he left college, but I did not keep posted in regard to his location or his business; but in the winter of 1844 and 1845 I spent over two months in New York City, and met Drs. Parker, Watts, Clark, Wooster, and many of my medical friends. I attended with Dr. Parker several medical meetings, and spent some evenings with Dr. Clark at his office, where he showed me many microscopical specimens, and how he made his examinations. From what I gathered at that time from Clark, Parker, and others, I was satisfied that Dr. Clark was the first man to use the microscope successfully in diagnosing disease in New York.

I mention these things because we were both Green Mountain Yankees, raised only a short distance apart among the snowdrifts of Berkshire County hills, and there is no one now, perhaps, but myself who can tell these items of his history; for he would hardly tell anyone that he was born and raised in a poor little country mountain town, and that his only sweetheart resided in the finest house in Williamstown, just across the street from the West College, and at her death his matrimonial prochivities, so far as I know, ended.

Alonzo Clark was a good, quiet, sensible, hard-working, man, who did much for the profession. Clark and Parker both wore themselves out by long-continued hard work, and as we say, they both died with the harness on. I studied medicine with Drs. Parker and Childs, and demonstrated for Dr. Parker four courses of anatomical lectures, one course at Woodstock, Vermont, and three at the Berkshire Medical School in Pittsfield. Dr. Watts was his demonstrator before me, but they are all gone now; only three of my college classmates are now living, and no doctor but myself is living who graduated at Williams College before the year 1834. But there are twenty-eight preachers living who graduated before that time, showing that preachers are much longer lived than doctors, for it is likely that as many students studied medicine as divinity.

Of my college class four are living, myself, two preachers, and a lawyer. Of Clark's class there are five living, four preachers and a teacher. So we all go, one by one.

Very respectfully,

JOHN FRISSELL, M.D.

52 Fourteenth Street, Wheeling, W. Va.

THE COLD WATER TREATMENT OF TYPHOID FEVER.

To the Editor of The Medical Record.

SIR: I have read with unusual interest the article on the treatment of typhoid fever by Dr. Baruch, published in your issue of February 16, 1889. The stupendous array of facts and figures there given certainly challenge attention, even if they do not carry universal conviction. It is to be feared they run too much athwart an easy-going routinism to do the latter. The popular prejudice against "cold water treatment," shared in no small degree by the profession, will probably continue to form a barrier to its general introduction, even under the most favorable circumstances. But typhoid fever, like most diseases of its class, flourishes most luxuriantly amid the squalor and filth of tenement-houses. In such houses there are neither the facilities nor the intelligence necessary to carry out such a line of treatment. If the wholesale slaughter of typhoid fever can be as nearly obliterated as these figures seem to indicate, then it may justly be said

that public charity should at once come to the rescue. But so long as the pauper sick are bandied about at the bidding of cheap ward politicians, or "knocked down" to the lowest bidder, as they are in Fort Wayne, there seems but little to hope for from this direction. In short, where the greatest need is the obstacles seem little less than insurmountable at present. Of course, this is a "job" for the humanitarian rather than the clinician; but the latter must take things as he finds them.

It would seem that Brand's prediction of a zero death-rate, contingent upon the commencement of treatment before the fifth day, is a very subtle refinement of therapeutics. The "cold water treatment" is not advised until the temperature reaches an elevation of 103° F. Now, a typical case of typhoid fever does not have such a temperature until the afternoon or evening of the fourth day. Hence the treatment is not advised until the fourth day, and yet it is fatal to a certain proportion if postponed until the fifth. It is certainly a very delicate adjustment of treatment when a patient is saved or doomed according as it is inaugurated on the fourth or the fifth day of a disease lasting a month.

That the alterations in Peyer's glands will not go beyond the stage of infiltration if treatment is instituted before this fateful "fifth day" is another prediction that raises very dubious questionings. This infiltration commences on the first day of the disease in a few glands, a few more being added each day as the disease progresses. It is hard to believe that necrosis can be entirely prevented after the fourth day, especially as the process is now known to be microbial in character. Patients recover, however, when the alvine discharges show the sloughs of many necrotic glands.

The principal criticism offered is that a little too much seems to be promised; but this is largely pardonable in the advocates of a method of treatment that has accomplished so much. One thing, however, seems clear, that unless the statistics quoted by Dr. Baruch can be offset by others or explained away (neither seeming an easy task), a new era has dawned in the history of typhoid fever. Our recognition of it appears to have been slow, but it ought not to be so from this time on. Let us look the facts squarely in the face. A mortality of only 1.7 per cent. in more than two thousand cases with strict cold water treatment, is an accomplished fact. If the present mortality of from twenty to forty per cent. continues, someone is responsible. If the physician is too blind to see the facts, or too timid to face a popular prejudice, the responsibility rests with him; if philanthropists will not provide the means for rescuing the indigent typhoid fever patient, it rests with them; while if the patient becomes recalcitrant, the matter is equally clear. Let it not be forgotten that if the present enormous fatality continues, it is, in the light of these facts, to be regarded as preventable loss of life; and that the responsibility rests somewhere, and is not difficult of location.

Respectfully,

G. W. McCarkey, M.D.

Fort Wayne, Ind., February 22, 1889.

"HOWARD'S METHOD" FROM A CLINICAL STAND-POINT.

To the Editor of The Medical Record.

Sir: I have read with interest your timely article in The Medical Record of February 23d, on the "Abuses of Etherization." Noting allusions in it, and in the discussion following its reading, to "Howard's Method" of treating suspended respiration, and having seen this method in practical use for several years, I think that possibly a few words on it from a clinical stand-point may not be amiss.

The articles which have appeared since Howard's was published in *The British Medical Journal* of November 17, 1888, show that forced extension of the head is not generally recognized as a remedy for dyspnœa or suspended respiration. As Howard states, the method is not "new." He uses this term in the title of his article because the explanation, viz., that forced extension of the head elevates the hyoid bone and the epiglottis, is the result of his recent work. Professor J. J. Chisolm, of this city, in an article on "Bromide of Ethyl" (*Marylana Medical Journal*, January 1, 1883), comparing ethyl and chloroform, says in regard to the latter: "Should loud snoring occur, force up the chin. This manipulation, by straightening the air-passages from the nose to the larynx, makes easy breathing. The forced elevation of the chin is far better in every respect than pulling out the tongue." In a monograph issued by him in the spring of 1888, he discusses this method more at length, attributing to "the overlapping of the epiglottis" difficulty in respiration, and the relief afforded by head extension to the fact, that by it "the whole front of the throat is pulled away from its posterior vertebral wall, giving the greatest amplitude to the laryngeal opening, and making a straight passage for the inspired air from the nose through the larynx into the lungs." He mentions some of the muscles connecting the inferior maxillary bone with the hyoid as being concerned in accomplishing this. He does not mention the hyo-epiglottic ligament, the "lower link" in the "chain," given by Howard.

In 1880, when I became Professor Chisolm's assistant, as a medical student, at the University of Maryland and at the Presbyterian Eye and Ear Hospital, what is now termed "Howard's method" was in constant use. Chloroform was the anæsthetic used for everything. In 1882 bromide of ethyl was substituted in very short operations, and the introduction of cocaine, in 1884, lessened, of course, the use of both drugs. So far as I can remember, ether has never been used at the hospital. During my nine years connection with the institution—for six of which I have been a member of the staff—I have not been unfortunate enough to see a death from anæsthetics. Should we ever happen to have a patient whose heart suddenly stops soon after the inhalation has commenced (due to sudden paralysis of the cardiac ganglia by the first vapor that reaches them, Bartholow), the exceptional record of our hospital will be broken. Such a case occurred in this city in 1883, and is reported by my friend, Professor J. Edwin Michael, in *The Medical News*, vol. xlii., No. 7. After a few inhalations the heart suddenly stopped, and could not be made to go again. No form of treatment that I know of could save a case like this. But the majority of deaths from anæsthetics do not occur this way. We read of sudden stopping of the respiration, or of a "gradual weakening" and "final cessation," of gradual "heart-failure," and so on. Pulling out of the tongue, cold-cloth flagellations, hypodermic injections, batteries, etc., are used to "rally the flagging vital forces," and at last death closes the scene. In your article you speak of the well-proven uselessness of all the above, and of some other means used to protect the patient. And this brings me to my real reason for writing this letter, to state how "Howard's method" is used at our hospital—with the result, we believe, of often preventing trouble during anæsthesia, and of curing it when it does occur.

A small pillow about ten inches long, six wide, and two thick, is placed under the patient's head at the commencement of the administration of chloroform. As he becomes unconscious this is withdrawn, and the head extended as far as possible without bringing it over the edge of the table. This is done whether respiration is easy or not. In the large majority of cases it remains easy and regular. The vital signs that are most carefully watched are the respiration and complexion. Not nearly as much importance is attached to feeling the pulse as to both of these. If our first alarm comes from the radial artery—*i.e.*, if the pulse suddenly stops—I do not believe much can be done. A close observation has convinced me that in most cases of "gradual heart failure," changes in the complexion, and in the regularity and depth of res-

piration, precede the "loss of arterial tone," "intermission of the pulse," and other things to which much importance is justly attached. I would not, however, undervalue the importance of watching the pulse, but I think that usually the face, or the respiration, will warn us of danger before the wrist will. If the face becomes livid, and the respiration stertorous, we extend, without an instant's delay, the head, to the utmost, over the edge of the table. Provided the respiration is full and regular, it does not seem to me that snoring is such a very dreadful thing as to demand the heroic measures you very justly condemn. Time and again have I seen this simple expedient restore easy breathing, and clear up a livid complexion.

In another class of cases we find a lessening in the depth of respiration, often preceded or accompanied by pallor. Soon the heart shows signs of trouble. The time to employ "Howard's method" is just as soon as this feeble respiration, or pallor, is noted. If we delay till the heart's action seems failing, we lose, I think, most valuable time. One or two deep inspirations will follow the extension of the head, and all will be well again. Just such a case occurred with me, while enucleating an eye, a few days ago. The breathing became feeble, with only partial expansion of the chest, while the head was extended on the table. Full extension at once fixed matters. If, in spite of this extension, the breathing does not at once become easy, and if the heart "fails" either after the respiratory and complexion changes, or simultaneously with them, the whole body is inverted, and head extension employed with the body in this position. My senior, Professor Chisolm, reported in your journal of January 21, 1888, a case illustrating this method of treatment.

These are practically the only methods we use. Only twice have I seen artificial respiration employed, and in only one of these cases—the little child whose case is the basis of Professor Chisolm's paper—do I think it did good. I believe it was largely instrumental in restoring this little fellow during his first collapse, though it was not employed later. I could mention many cases in which I have seen relief follow head extension, and several where difficult or stertorous respiration followed slight flexion from the extended position. My object, however, in writing is to try to emphasize, first, that head extension is serviceable in *keeping breathing* easy; and, second, that to relieve apnœa or dyspnœa it must be employed as soon as the signs of either appear.

Very truly yours,

HIRAM WOODS, M.D.,
Assistant Surgeon at Presbyterian Eye and Ear Hospital.
527 N. HOWARD STREET, BALTIMORE, MD., March 9, 1889.

A COMMISSION ON THE TREATMENT OF DISEASES OF THE LOWER ANIMALS has just concluded the first stage of its inquiries at the Ministry of Agriculture in Rome. The diseases to which oxen, sheep, and pigs are specially prone were considered in their therapeutic as well as prophylactic relations, and the reports embodying the results of investigations by experts were submitted to the Commission. Inoculation for charbon, on the Pasteur system, was the subject of animated discussion, resulting in not a little divergence of opinion; and so the commission voted to conduct an elaborate inquiry with reference to establishing the value or otherwise of the method.

THE INFERIORITY OF THE LEFT SIDE OF THE BODY.—Dr. Henry Duchenne has drawn up a list of the disorders which especially affect the left half of the body, and concludes therefrom that it possesses a biological inferiority to the right. He says obliterating arteritis affects the left Sylvian artery oftener. Tubercle affects the left lung oftener; calculous nephritis and renal cysts the left kidney; ovaritis the left kidney; orchitis the left testicle; varicocele the left spermatic veins; neuralgia; chorea, hysterical anæsthesia, the left side; cancer of the breast the left mamma.

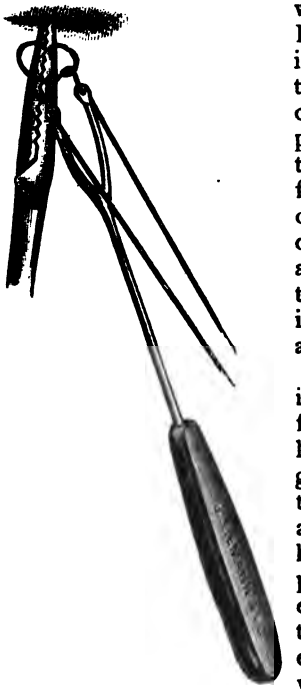
New Instruments.

A NEW KNOT-TIER.

BY CHARLES D. SCUDDER, M.D.,
NEW YORK.

THE accompanying cut represents an instrument devised by me to help in making knots, when suturing or ligaturing, in cavities.

The instrument consists of a two-pronged steel shaft with a baked-rubber handle. Each prong has an eye near its end, and the distance between the eyes is three-eighths of an inch. The form of the prongs has been changed since the drawing was made, and the fork is now lyre-shaped. It can be made curved to any degree desired. The holes are carefully bevelled, and three sizes—nine-inch, six-inch, and four-inch length—are made by Tiemann & Co.



In ligaturing, the first knot is carried over the hæmostatic forceps, and the ends of the ligature (which should be of good length) are passed through the holes in the fork, as shown in the sketch. The knot is carried down and placed by the knot-tier wherever wished, and suitable traction is made by pulling on the ends of the ligature, which are wrapped around the fingers of either hand, while steadying the handle with the thumbs. The instrument is then removed carefully, in order not to undo the knot; a new hitch, single or double, is made, the ends again threaded through the eyes, the knot placed, and firm traction completes the operation.

In suturing, the needle is detached after the suture is passed through the tissues to be sewn together, and the knot is made and placed as above described.

A little practice will enable the operator to apply knots quickly and surely.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 3 to March 9, 1889.

WEBSTER, WARREN, Major and Surgeon. Retired from active service February 28, 1889. Par. 9, S. O. 50, A. G. O., March 1, 1889.

Official List of Changes in the Medical Corps of the United States Navy for the week ending March 9, 1889.

MARSTILLER, E. H., Passed Assistant Surgeon. Detached from Monitors at Richmond, and to wait orders.

CABELL, A. G., Passed Assistant Surgeon. Detached from the Naval Hospital, Chelsea, Mass., and ordered to Monitors at Richmond.

MCCLURG, WALTER A., Passed Assistant Surgeon. Promoted to rank of Surgeon.

BABIN, H. J., Surgeon. Detached from the Mohican, to proceed home, and await orders.

BRADLEY, G. P., Surgeon. Ordered to the Mohican.

LUNG, GEORGE A., Assistant Surgeon. Detached from the Vermont, and ordered to the Mohican.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 9, 1889:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	6	2
Scarlet fever	366	51
Cerebro-spinal meningitis	5	2
Measles	258	21
Diphtheria	207	53
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

THE DIAGNOSIS AND MEDICAL TREATMENT OF ACUTE INTESTINAL OBSTRUCTION.—Of the many conditions formerly treated exclusively by the physician, but recently brought within the province of the surgeon, intestinal obstruction in its various forms is one of the most important, and although Dr. R. H. Fitz (*Boston Medical and Surgical Journal, and American Journal of the Medical Sciences*) limits himself chiefly to the consideration of the medical treatment, his conclusions are, on that account, no less interesting to the surgeon. After analyzing the symptoms of strangulation, intussusception, twist, gall-stone, strictures, tumor, etc., he concludes that the symptoms, apart from the stoppage of the bowels, upon the presence of which the physician must rely to establish a diagnosis of acute intestinal obstruction, are abdominal pain, nausea, or vomiting, abdominal tympany, and abdominal tumor. The presence of fever, the occurrence of hiccough or jaundice, abnormal conditions of the urine, are all occasional and subordinate. The cardinal symptoms are pain, vomiting, tympany, and tumor. The vomit may become fæcal, and the tumor may be simulated by visible intestinal coils. But the presence of these cardinal symptoms is evidence of other disease than acute, internal, mechanical obstruction of the bowels. They may result from external causes of obstruction, and the various herniæ are to be excluded. They may be the symptoms of a peritonitis in the absence of mechanical intestinal obstruction. The various causes of peritonitis are, therefore, to be excluded. It is important to remember that, in the presence of urgent symptoms of acute obstruction, the source is found in the lower abdomen in more than four-fifths of the cases. The physician should remember that in the light of exact knowledge nearly all cases of acute, mechanical, intestinal obstruction die, unless relieved by surgical interference; that curative medical treatment has proven of sure avail in only a limited number of cases of intussusception, possibly in a few of twist in the large intestine, and in certain cases of gall-stones in the small intestine; that his first duty, after relieving pain, is to determine the capacity of the large intestine; that this is best accomplished during the first two days following the initial pain, before tympany makes the task more difficult, and pathological changes cause it to be more dangerous; finally, that the means employed for this purpose represent the most efficient curative agent in his control. Notwithstanding that thirty-one per cent. of the cases recovered without any operative treatment, it does not follow that such a recovery is to be anticipated, especially if it is to be associated with the evacuation of a slough. In such cases, in addition to possible death from peritonitis, annular stenosis may occur, or strangulation from lymph-bands may occur. The medical treatment of intussusception consists essentially in the use of mechanical measures for the reduction of the displaced portion of the bowel. The beneficial effect of such measures is all the more possible since it is evident that spontaneous reduction may occur. The mechanical treatment consists of rectal injection or inflation, preferably the former, and replacement by a repositor. Almost indispensable advantage is to be derived from the associated use of anæsthesia. Massage of the tumor and inversion of the body are important adjuncts. In the medical treatment of obstruction from gall-stones, it is to be remembered that in the cases here collected a fatal result followed all surgical treatment after the first week, and that five cases recovered under medical treatment after this date. The condition of the patient alone must determine the nature and duration of the treatment. Opiates, cathartics, and electricity have all been used in cases ending with recovery. In the light of the published experience of the past eight years, the medical treatment of acute obstruction is limited to the use of injections during the first three days, under sufficient degrees of pressure within fixed limits, to determine the patency of the large intestine. If it proves impassable, the case is no longer medical, but surgical. If the large intestine is readily distended, and a diagnosis of gall-stones is admissible, and the condition of the patient is not urgent, opium is to be given; laxatives and electricity may be tried, but they are of doubtful expediency. If medical treatment is of no avail, and surgical treatment is refused, the efforts of the physician are restricted to the relief of pain and distress by narcotics, intestinal punctures, and gastric siphonage. In conclusion, acute intestinal obstruction is diagnosticated by exclusion. Its seat is fixed by injection. Its variety is determined by its seat, the age, antecedents, and symptoms of the patient. Its treatment is surgical, on or after the third day, if the symptoms are urgent and forced injections fail to relieve.

CAMPHORIC ACID—$C_8H_{14}(CO.OH)_2$—has been recommended as an anti-catarrhal, as a dermatic, and as an anti-diaphoretic. A paper recently read by Dr. M. Reschert before the Berlin Medical Society attributes to this acid, which hitherto had no therapeutic use, an eminently beneficial effect in both acute and chronic inflammatory affections of the mucous membranes of the entire respiratory tract. Likewise in various acute diseases of the skin. A topical application of a three to six per cent. solution of camphoric acid effects a contraction of the surface-tissue (dermis or mucous membrane) within as little as two minutes—thus immediately causing a sensation of relief and palliation of pain, which phenomena are combined with an essential reduction of the inflammatory symptoms—acute coryza has repeatedly yielded to the nasal douche charged with a solution of 1 in 500, or to a cotton-wool tampon with a two per cent. solution. The acid exhibits no caustic accessory effects; on the contrary, it actively promotes granulation (in laryngeal ulcerations, etc.); and solutions of but 0.9 of one per cent. act aseptically. It may be exhibited subcutaneously; or topically in a one-half to one to two per cent. solution; or as an inhalant in a one to two per cent. solution. The probabilities are, that this substance may prove beneficial also in other directions besides those named. Tuberculous processes, however, are not influenced by it. Dr. Furbringer reports its prompt efficacy—in at least fifty per cent. of the cases treated—in stopping the night-sweats of consumptives. He uses, for this purpose, either 1 gramme (15 grains) three to four times through the day; or 2 grammes in the evening. This is said by Dr. Furbringer to be the only specific action possessed by camphoric acid, which he terms "an agreeable, very slightly toxic, and very little irritant antiseptic." Camphoric acid is in thin, colorless, scale-like crystals; or in large, limpid, monoclinic crystals, of acid taste; melting-point, 178° C. (352.4° F.); little soluble in water—easily so in alcohol or ether. Fats and oils dissolve up to two per cent. of it.

ANTIPYRIN IN CHORDEE.—Dr. Dixon recommends antipyrin in doses of fifteen grains at bed-time as a very efficient preventive of chordee.

THE ETIOLOGY OF CROUPOUS PNEUMONIA.[1]

BY GEORGE M. STERNBERG,

MAJOR AND SURGEON, UNITED STATES ARMY.

(Continued from page 285.)

PART II.

THE PRESENCE OF M. PASTEURI IN THE SALIVARY SECRETIONS OF HEALTHY INDIVIDUALS.

IN September, 1880, while engaged in investigations relating to the etiology of the malarial fevers, I injected a little of my own saliva beneath the skin of two rabbits, as a control experiment. To my surprise the animals died, and I found in their blood a multitude of oval micro-organisms, united for the most part in pairs, or in chains of three or four elements. These experiments are recorded in my paper entitled "Experimental Investigations relating to the Etiology of the Malarial Fevers," published in the Report of the National Board of Health for 1881, pp. 74 and 75.

In December of the same year Pasteur observed this micrococcus in the blood of rabbits which died (December 13th) as a result of an inoculation with the saliva of a child which died of hydrophobia in one of the hospitals of Paris.[2]

Following up my experiments made in New Orleans (in September, 1880), in Philadelphia (January, 1881), and in Baltimore (March, 1881), I obtained the following results:

"The saliva of four students, residents of Baltimore (in March) gave negative results; eleven rabbits injected with the saliva of six individuals in Philadelphia (in January) gave eight deaths and three negative results; but in the fatal cases a less degree of virulence was shown in six, by a more prolonged period between the date of injection and the date of death. This was three days in one, four days in four, and seven days in one."[3]

The fact that the micrococcus in question varies very much as to its pathogenic power, as a result of conditions relating to the medium in which it develops, etc., was insisted upon in the paper from which I have quoted, and has been fully established by later researches (Fränkel, Gamaléia).

I found that cultures which had been kept for one or two weeks no longer exhibited any virulence when injected beneath the skin of a rabbit. On the other hand, virulence was increased by passing through the rabbit. This is shown by the following quotation from the same paper:

"In the dog the vital resistance is competent to withstand the assaults of the micrococcus—injected subcutaneously—having the potency of those found in my saliva, and the result of such an injection is simply a circumscribed abscess. But the increased power (which is perhaps simply a more vigorous and rapid development) gained by cultivation in the body of the rabbit, enables these organisms to overcome the resistance of the dog, and a diffuse cellulitis results of a fatal character." This result was obtained in a single experiment in which one c.c. of serum from the subcutaneous cellular tissue of a rabbit recently dead was injected beneath the skin of a dog.

Again I say in the same paper: "Unfiltered serum from a recently dead rabbit has invariably proved fatal in smaller quantity and in less time than is required by the saliva in the first instance, showing an increase of virulence as the result of successive cultivation of the organism in the body of a susceptible animal."

Claxton,[1] in a series of experiments made in Philadelphia in 1882, injected the saliva of seven individuals into eighteen rabbits. Five of these died within five days, and nine at a later period.

In a paper published in the *Journal of the Royal Microscopical Society* (June, 1886), I say:

"My own earlier experiments showed that there is a difference in the pathogenic potency of the saliva of different individuals, and I have since learned that the saliva of the same individual may differ in this respect at different times. Thus, during the past three years injections of my own saliva have not infrequently failed to cause a fatal result, and in fatal cases death is apt to occur after a somewhat longer interval, seventy-two hours or more; whereas in my earlier experiments, the animals infallibly died within forty-eight hours."

Fränkel, whose first publication was made in 1885, discovered the presence of this micrococcus in his own salivary secretions in 1883, and has since made extended and important researches with reference to it.

The saliva of five healthy individuals and the sputa of patients suffering from other diseases than pneumonia, injected into eighteen rabbits, induced fatal "sputum septicæmia" in three only.

When he commenced his experiments his saliva was uniformly fatal to rabbits, but a year later it was without effect.

Wolf[2] injected the saliva of twelve healthy individuals, and of three patients with catarrhal bronchitis, into rabbits, and induced "sputum septicæmia" in three.

Netter[3] examined the saliva of one hundred and sixty-five healthy persons, by inoculation experiments in rabbits, and demonstrated the presence of M. Pasteuri in fifteen per cent. of the number.

Vignal,[4] in his recent elaborate paper upon the micro-organisms of the mouth, says:

"Last year I encountered this microbe continually in my mouth during a period of two months, then it disappeared, and I did not find it again until April of this year, and then only for fifteen days, when it again disappeared without appreciable cause."

Immunity.—With reference to the question of immunity from pneumonia when the specific agent of this disease is present in the salivary secretions; or the failure, in many cases, to extend from the invaded lobe to other portions of the same lung, Gamaléia offers the following explanation:

"In order to study better the mechanism of the immunity of the healthy lungs in presence of the streptococcus Pasteuri, we made the microscopic analysis of the sputa

of an individual who, in the month of December, 1887, experienced an attack of fibrinous pneumonia under our observation, and who subsequently had a chronic bronchitis, and expectorated constantly a quantity of pneumonic microbes, virulent for rabbits.

"The sputa were of mucus and adhered to the vessel; under the microscope they presented almost a pure culture of the specific streptococci, some polynuclear globules, and the large cells called endothelial (Staubzellen), having a large, round nucleus and filled with granules. Attentive examination showed that the last-mentioned cells, which have quite the character of macrophages, contained enormous quantities of streptococcus Pasteuri in various stages of disintegration. One may find in the same cell typical diplococci mingled with contracted and angular forms that by comparison alone can be assimilated with the specific microbes. In this way one may be convinced that the débris contained in the macrophages is the remnant of pneumonic microbes. The polynuclear leucocytes also contained the streptococcus lanceolatus, but in much smaller quantity.

"These phenomena give us, it seems to me, the explanation sought of the immunity of the pulmonary tissues. The pathogenic microbes, even when they exist in a very great quantity in the bronchial mucus, and arrive in the pulmonary alveoli, are arrested there in their development by the macrophages (Staubzellen), which take them in and digest them. In this struggle the endothelial cells may also die and be iejected in the sputa" (loc. cit., p. 457).

This explanation, in accordance with the so-called "Metschnikoff theory," has been offered by the writer in an attempt to explain immunity from infectious diseases generally, at a date which I believe to be prior to the publication of Metschnikoff's first paper. And it was the observation of the presence of the same micrococcus in the leucocytes of inoculated rabbits that led me to this explanation. In support of my statement I quote from my published works as follows:

In a paper read at the meeting of the American Association for Advancement of Science in Cincinnati, August 18, 1881,[1] I say: "It has occurred to me that possibly the white corpuscles may have the office of picking up and digesting bacterial organisms when by any means they find their way into the blood. The propensity exhibited by the leucocytes for picking up inorganic granules is well known, and that they may be able not only to pick up but to assimilate, and so dispose of, the bacteria which come in their way, does not seem to me very improbable in view of the fact that amœbæ, which resemble them so closely, feed upon bacteria and similar organisms."

In a paper,[2] published in the *American Journal of the Medical Sciences* in 1881, after showing that Pasteur's "exhaustion theory" of immunity is untenable, I say:

"The view which I am endeavoring to elucidate is that, during a non-fatal attack of one of the specific diseases, the cellular elements implicated which do not succumb to the destructive influence of the poison, acquire a tolerance to this poison which is transmissible to their progeny, and which is the reason of the exemption which the individual enjoys from future attacks of the same disease."

In my chapter on "Bacteria in Infectious Diseases," in "Bacteria,"[3] published in the spring of 1884, but placed in the hands of the publishers in 1883 (preface dated August 15, 1883), I say:

"In the disease produced by inoculation with saliva, or with a culture-fluid containing the micrococcus under consideration, owing perhaps to the rapid development of the micrococcus, no such limiting wall of inflammatory exudation is established; and we find the subcutaneous connective tissue diffusely infiltrated with serum which swarms with the parasites.

"The failure to restrict the inroads of the parasite may not be due alone to its power of rapid multiplication. It is not improbable that some poison is produced, during its active growth, which lowers the vital resistance of the tissues and prevents the occurrence of adhesive inflammation. And it may be that the true explanation of the immunity afforded by a mild attack of an infectious germ disease, is to be found in an acquired tolerance to the action of a chemical poison produced by the micro-organism, and consequent ability to bring the resources of nature to bear to restrict invasion by the parasite."

The theory of immunity, here clearly stated, has subsequently received strong support from the experiments of Salmon (1885) in this country, and of Roux[1] in Pasteur's laboratory.

But, does a single attack of acute lobar pneumonia afford any protection from subsequent attacks? This question may be divided into two: Is that portion of the lung invaded in a first attack, subject to a similar process at a subsequent date? Is the individual who has suffered an attack of fibrinous pneumonia, subject to a second attack? The second question—if we speak of pneumonia in a general way, not differentiating catarrhal pneumonia from acute fibrinous pneumonia—must be answered in the affirmative, for that second attacks of pneumonia may occur cannot be questioned.

As to acute lobar pneumonia, which we have learned to look upon as a specific infectious disease, I am not able to give a definite answer from my own experience, or from an examination of the literature at hand, and the question is here stated for the purpose of eliciting information.

MORPHOLOGICAL AND PHYSIOLOGICAL CHARACTERS.—Figures 1 and 2 are from camera lucida drawings, and represent the organism as it appears in the blood of an infected rabbit, or in active growth in a suitable culture medium, when stained with one of the aniline colors. Although when in active growth the elements are of an oval or lance-oval form, this micro-organism is nevertheless a micrococcus, or according to the classification of Zopf, a streptococcus; for it approaches the spherical form in old cultures, in which the development is tardy or has ceased altogether, and in surface cultures upon agar-agar is often seen in long chains, as in Fig. 3. In blood, and in recent cultures in a liquid medium, it is commonly seen in pairs or in chains of three or four oval elements. The appearance of a capsule seen in Fig. 4 is far from being constant, and is best seen in preparations made from the blood of an animal recently dead, or in the rusty sputum of pneumonia. In unstained preparations, this so-called "capsule" appears as an aureole or transparent envelope, which can only be seen with difficulty owing to the fact that its refractive index very nearly approaches that of the fluid in which it is immersed. In-

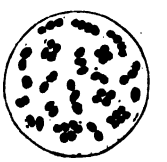

FIG. 1.—Micrococcus Pasteuri from blood of rabbit inoculated subcutaneously with normal human saliva (Dr. S.). Magnified 1,000 diameters.

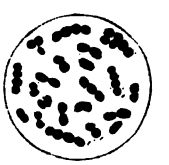

FIG. 2.—M. Pasteuri from blood of rabbit inoculated subcutaneously with fresh pneumonic sputum from a patient in the seventh day of the disease. Same amplification as Fig. 1.

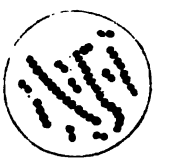

FIG. 3.—Surface culture of M. Pasteuri, showing development of long chains. Same amplification.

FIG. 4.—Surface culture of M. Pasteuri from blood of rabbit injected with pneumonic sputum, showing the so-called "capsule." Same amplification.

my first paper, which is illustrated by photo-micrographs (1881), I say:

"When a culture-tube containing bouillon, made from the flesh of the rabbit, is inoculated with a minute quantity of blood taken from a rabbit recently dead, and containing the organism shown in Fig. 1" (a photo-micrograph showing it in rabbit's blood) "is placed in an incubating oven at a temperature of 37° C., there is a rapid multiplication of the micrococcus, which, it is proved experimentally, retains its virulent properties. While in process of active multiplication the organism also retains, at least to some extent, its characteristic form, as shown in Fig. 1, and presents the appearance of being surrounded by an aureole, as already described. But in a limited amount of the culture-fluid the process of multiplication by fission soon ceases.

"When the liquid is examined during the first few hours after inoculation, it is seen to be slightly opalescent, and upon microscopical examination is found to contain, distributed through it, an abundance of micrococci, solitary, in pairs, and in short chains. At a later period (forty-eight hours) the micrococcus will be found chiefly at the bottom of the fluid, in groups and zooglea masses, and without the transparent aureole which characterizes it, especially in the blood of the rabbit, during its active multiplication. If a culture-fluid in which the micrococcus has been present in abundance be examined at a later date (one or two weeks), the organism will no longer be found, at least in a recognizable form, and, so far as my experiments go, the culture-fluid no longer exhibits any virulence when injected beneath the skin of a rabbit."

FIG. 5.—Copied from illustration accompanying the paper of Dr. G. Salvioli in the *Archivo per le Scienze Mediche*. Turin, vol. viii., Tav. viii., Fig. 2. "Cells of the pleuritic exudation containing pneumonia-cocci, mounted in Canada balsam." Stained with gentian-violet.

M. Pasteuri is not motile, and does not, so far as known, multiply in any other way than by simple binary division. Its thermal death-point, as fixed by myself in 1881, is 140° F. (60° C.), the time of exposure being ten minutes. The facts that it does not grow at temperatures much below that of the human body, and that it requires for its development a neutral or slightly alkaline culture-medium, and is quickly destroyed in fluids undergoing putrefactive decomposition, indicate that it is a true parasite, in the human mouth or elsewhere, and that it is unable to maintain a saprophytic existence externally to the bodies of warm-blooded animals.

In my experiments on disinfectants in which this micrococcus served as the test-organism, made in Baltimore in 1881 (loc. cit.), and in San Francisco in 1883 (loc. cit.), I obtained the following results:

Mercuric chloride—One part in 20,000 destroys the vitality of the micrococcus in bouillon cultures, and one part in 40,000 arrests development. Iodine, dissolved by potassium iodide—1 : 1,000 destroys vitality; 1 : 4,000 arrests development. Sulphuric acid—1 : 800 destroys vitality; 1 : 1,600 arrests development. Carbolic acid—1 : 500 destroys vitality. Zinc chloride—1 : 100 destroys vitality. Alcohol—twenty-five per cent. required to destroy vitality. Salicylic acid—four per cent.; sodium hyposulphite, eight per cent.; ferric sulphate, sixteen per cent.; boracic acid, four per cent.; sodium biborate, four per cent.; and sodium salicylate, four per cent. were found not to destroy vitality. The time of exposure in these experiments was two hours.

In my experiments made in Baltimore (1881), in which the blood of a rabbit recently dead from an inoculation with material containing this micrococcus, was subjected to the action of the disinfecting agent for half an hour, and then injected into another rabbit, I found that certain chemical agents—sodium hyposulphite and alcohol—when mixed with the septic blood modified its virulence without destroying the vitality of the micro-organism; and that the inoculated animal recovered after such an inoculation, and was subsequently immune from the effects of the unattenuated virus. I believe that the experimental evidence here referred to is the first recorded with reference to the attenuation of virus by chemical reagents. This fact is recognized by the French author Vallin, in his "Traité des Désinfectants," published in Paris in 1882 (p. 222).

On the surface of agar jelly M. Pasteuri forms a slightly elevated, nearly transparent growth, and in "stick-cultures" in the same materia grows, to a limited extent, along the track of the needle, forming a nebulous line.

The results obtained by Fränkel with reference to the influence of various temperatures on the pathogenic power of this micrococcus, are as follows: In fluid media a temperature of 42° C., maintained for two days, suffices to neutralize the virulence of the culture. The same result is obtained at a temperature of 41° C., maintained for four or five days. Between 39.5° C. and 40.5° C., the virulence is no longer abolished, but is so far modified that inoculations no longer give rise, in the rabbit, exclusively to the typical condition of the blood and enlarged spleen of septicæmia, but simultaneously to an intense localization of the virus in the serous membranes of the heart and lungs.

Netter has shown that rabbits which recover after receiving an injection of saliva containing this micrococcus, are subsequently immune from the form of septicæmia to which it gives rise. According to this author the saliva of convalescents from pneumonia, during the first two or three weeks, is less virulent than that collected at a later date, and animals inoculated with it usually recover and are subsequently immune. Fränkel, also, found that the micrococcus, although still present in the sputa of convalescents from pneumonia, no longer presents the same degree of virulence, and that death may occur as late as the sixth day after the inoculation is made, instead of within twenty-four to forty-eight hours, as is the case when the rusty sputum of acute pneumonia is injected.

NAMES.—The writer first named this micro-organism Micrococcus Pasteuri, in a paper published in the *American Journal of the Medical Sciences*, in July, 1885. This name has generally been adopted in this country, and is used by recent English and French authors, but the German authors have not accepted it. Thus Flügge briefly describes it under the name "Bacillus septicus sputigenus (Fränkel)," thus ignoring all the work which had been done upon it prior to the time that Fränkel commenced his researches. Biondi,[1] following Flügge's classification, calls it "Bacillus salivarius septicus."

Fränkel speaks of it as the "Micrococcus of sputum septicæmia," or, as the "lancet-shaped pneumonia coccus."

Weichselbaum, and other German authors, frequently speak of it as "Fränkel's pneumonia coccus," or as the "diplococcus pneumoniæ." Gamaléia, recognizing it as a streptococcus, as the writer had done previously,[2] calls it "Streptococcus lanceolatus Pasteuri." I do not object to this modification of the name which I felt authorized to give to this much-named microbe in 1885, and which has all the rights of priority. But I do object to the designation "Fränkel's diplococcus," or "Fränkel's pneumonia coccus," which so many German writers have seen fit to apply to it. While I fully recognize the value of Fränkel's contributions to our knowledge with reference to its presence in pneumonic exudate, etc., I must insist that Talamon deserves the credit of having first produced

[1] Zeitschrift für Hygiene, Bd. 11, 1887, Heft. 2, p. 194.
[2] See my paper in the Journal of the Royal Microscopical Society June, 1886, p. 396.

typical lobar pneumonia in rabbits, by injecting this micrococcus through the thoracic walls. We have most positive evidence of this fact in the quotation already made from the work of Professor Germain Sée, published in Paris in 1885. If, therefore, it is anyone's pneumonia coccus, it is Talamon's. And in view of the fact that I discovered it in 1880, photographed it, and described its morphological characters in 1881, and made extended researches relating to its physiological characters, resistance to heat, to chemical agents, etc., in 1881 to 1883, I think I may properly object to its being called "Fränkel's diplococcus," or "Fränkel's micrococcus (or bacillus) of sputum septicæmia."

Having thus briefly reviewed the history of our knowledge with reference to this interesting micro-organism, and shown the nature of the evidence upon which it is claimed, by several competent bacteriologists, to be the infectious agent in acute pneumonia, I must leave the subject for your consideration and for further experimental investigation.

THE RADICAL CURE OF INGUINAL HERNIA.[1]

By CHARLES McBURNEY, M.D.,

SURGEON TO THE ROOSEVELT HOSPITAL, NEW YORK.

MR. PRESIDENT: When I reflect how much has been said and written during the last few years on the subject of the operative treatment of hernia; still more, as I realize the perfection to which many surgeons have, by different methods, brought this operative treatment, I may well hesitate to ask your attention to my limited experience in the same direction. Nevertheless, as we are all actuated by the same motive, that is, the desire to solve some difficult problems, I venture to offer my contribution as the result of no little thought and labor. In May, 1886, a patient came under my charge at St. Luke's Hospital, who had been operated upon some months before, by one of my colleagues, for the relief of a large scrotal hernia. He came to me on account of a protrusion through the abdominal wall, situated about one-half inch above the internal abdominal ring on the left side. This protrusion, or ventral hernia, was about the size of a half-egg, and evidently separated the fibres of the external oblique aponeurosis at that point. The base of the tumor was much larger than its apex, and its depth small, so that I hoped by simply reducing or pushing back the shallow pouch and firmly closing the opening in the abdominal wall to obtain a cure. I did not believe, however, that simply sewing together the parallel fibres of the aponeurosis and then closing the wound would cause them to remain attached with any firmness. I therefore completely cleared the edges of the opening in the abdominal wall down to the level of the peritoneum, brought the two walls of the wound moderately near together, and filled the interval with iodoform gauze, intending thereby to secure the formation of a dense cicatricial bond of union from the peritoneum outward, and so insure a firm union between the corresponding layers on the opposite sides of the wound. In this I was successful, for a dense strong cicatrix, perhaps one-fifth or one-sixth of an inch wide, was formed.

The patient got up from bed well, but in a very short time the hernia returned. I accounted for this relapse by the fact that I had not removed the redundant peritoneum. I had left a lax peritoneal pouch with some loose connective tissue outside it, thus providing the conditions necessary for the formation of a hernia. My conviction in regard to the cause of relapse in this case was confirmed by a similar experience in two other cases, in both of which indirect inguinal herniæ, the peritoneal sac was unintentionally reduced during the operation, and was not afterward found and removed. In both of these cases recurrence of hernia occurred shortly after convalescence. These cases still further strengthened my conviction, one which almost all surgeons hold, that the essential indispensable step in all operations for the radical cure of hernia is the complete removal of the sac, that is, the restoration to the peritoneal surface of the abdomen, at the point where the hernia begins, of the same smooth, tense condition, that exists at other parts of the inner lining of the abdominal walls. This proposition will, I think, be conceded by all who have had experience in the operative treatment of hernia. It is well known that in laparotomies where large drainage-tubes are used for a considerable period the subsequent appearance of ventral hernia is much more frequent than where no tube is used, as in clean ovariotomies. In the first class of cases no peritoneum covers the site of the drainage-tube, but a dimple is left on the inner aspect of the cicatrix which invites a protrusion of intestine or omentum, and which rapidly enlarges under pressure. In the second class, the clean ovariotomies, where the walls are neatly brought together and where no drainage is used, a smooth, tense peritoneal surface lines the cicatrix, and ventral hernia rarely follows. In the formation of inguinal hernia the first predisposing and inviting cause is the slight pouch or pocket formed by the peritoneum as it is reflected over the upper part of the spermatic cord in the male, and over the round ligament in the female, at the point where this cord enters the internal abdominal ring. The loose connective tissue which accompanies the cord, and fills the inguinal canal, forms no substantial backing to the peritoneum at this point, hence a protrusion which is at first a tiny pocket readily grows under the great and constant pressure from within to a fully developed inguinal hernia.

If these statements are correct, it follows, as a matter of course, that to cure hernia radically, one must radically remove the predisposing cause, namely, peritoneal laxity at the internal ring, and then must efficiently support the peritoneum at this point. Most surgeons agree as to the importance of these steps, the only difference of opinion being as to the means to be adopted.

Reasoning in this manner most surgeons have given up as totally unreliable all of the older methods, such as depended upon the inversion of pouches of skin into the inguinal canal, the use of subcutaneous sutures, and that last most unscientific method, the injection into the connective tissue outside the sac, of irritating fluids. Many have been contented, and still are so, with removing that portion of the sac which lies below the external ring, deliberately leaving undisturbed that portion of the sac which lies in the canal between the external and the internal rings; or else have, as it is described ofter, "pulled the sac well down." Of course the upper part or neck of the sac is never removed by this method. These operators devote most attention to sewing up the external ring with various kinds of sutures, ignoring the fact that a hernia coming down into the canal is quite capable of breaking down any suture or cicatrix that may lie below it. The recognition of this radical defect in operating led to different methods devised to totally obliterate the sac. Macewen's method consists in first dissecting out the sac completely, then, by means of a suture passed lengthwise through the sac, this is thrown into a series of folds, the folded mass being, to use Macewen's words, "completely reduced from the canal into the abdomen, constituting a pad which is placed on the peritoneal surface opposite the internal ring. It there constitutes a boss or bulwark with its convexity presenting backward toward the abdomen, while its base rests on the abdominal walls surrounding the circumference of the internal ring."[1] This method, when practicable, undoubtedly obliterates the sac, but if it produces a "boss or bulwark" with an inner convexity, it, of course, tends to form an everted angle or pouch around the margin of this convexity. It does not reproduce the desired smooth, natural,

[1] Read before the New York Academy of Medicine, February 21, 1889.

[1] Annals of Surgery, vol. iv., p. 91.

peritoneal surface. Moreover, this method is often extremely difficult of application, or totally impracticable, as, for instance, in congenital herniæ; in cases where the sigmoid flexure or caput coli prolapses, and the uncovered wall of the intestine forms part of the sac wall; in cases where the sac is injured or so diseased that it is unfit to replace; and in cases, as in children, where the sac, being very small and thin, the whole mass of the folded sac is no larger than a pea. In selected cases this method has rendered remarkable results, due, I much believe, to the obliteration of the sac, and not to the formation of a boss or bulwark.

The same motive, that of totally obliterating the sac, led Mr. Charles Ball, of England, to devise the method of twisting the sac, the sac being seized high up in the canal with forceps, and twisted a number of times upon itself, the design being to twist the sac until its tubular character is entirely destroyed, and the peritoneum around the internal ring is thrown even into radiating folds. This somewhat blind method can hardly commend itself to a careful surgeon, for no provision is made against the involvement in the twist of a portion of perhaps already adherent intestine or omentum, and the sac may easily be twisted so much as to rupture it, or so little as to fail to obliterate it. Moreover, the application of this method presupposes a perfect, twistable sac, and is impracticable in the class of cases mentioned above as unsuitable for Macewen's plan.

It has seemed to me clear that to reach and operate upon the extreme upper part of the neck of the sac with certainty and safety the surgeon should expose it fairly, and I thought that I had devised the plan for doing so. I subsequently learned, however, that I had been anticipated in this, by many years, by Otto Riesel,[1] who, with the same design, advised and practised splitting the anterior wall of the canal quite to the internal ring. The advantage of doing this, in order to enable one to reach the highest part of the sac, and there openly deal with it, is self-evident. There are other advantages obtained by this plan which I shall refer to later. When the anterior wall of the canal is split up to, and a little beyond, the internal ring, one can make use of either of two methods of dealing with the neck of the sac. It may be either tied securely with a stout catgut or silk ligature, the sac being always opened to demonstrate that no portion of intestine or omentum is included in the ligature, or in the class of cases referred to as unsuitable for Macewen's or Ball's method, the sac may be—whether congenital or injured, or otherwise imperfect—cut away and the neck neatly and smoothly sewed. In this manner it is very easy to restore to the peritoneum at the internal abdominal ring, its natural, smooth, unbroken surface. My friend Dr. Abbe tells me that he has once had an opportunity to see the effect upon the peritoneal aspect of the internal ring which was produced by the application of a ligature as described.

A patient who had been operated upon in this manner died from other causes some time after operation, and at the autopsy the inner aspect of the internal ring showed a perfectly smooth surface, marked by a single central punctate cicatrix. In all cases where applicable, I much prefer the ligature, as being more rapid and perfect than the suture.

The sac having been dealt with by one method or another, various plans have been adopted in the treatment of the canal. Now this is undoubtedly the second most important step. The smooth internal peritoneal surface at the internal ring is of great value, but this should have some backing or support applied to it. Many are satisfied to supply that support at the external ring, entirely ignoring the canal.

This is done by sewing together the pillars of the external ring, a very imperfect method for several reasons. In the first place, there is still room for an incomplete hernia above the closed external ring, and if a bubonocele or incomplete hernia exists, and no truss is worn, no closure of the external ring can prevent the descent of the hernia through the ring. Moreover, the natural arrangement of the aponeurotic fibres forming the pillars of the ring is such that these diverge from one another. The ordinary tension of the abdominal wall tends to keep this ring open, doubtless to protect the cord from constriction, and therefore any sutures which draw the edges of this external ring together must inevitably give way, or, if they do not give way, must inevitably cut through the tense pillars. Is it not also entirely irrational to suppose that the extremely thin, nearly parallel, edges of this ring can be made to grow strongly together by simply suturing them? Certainly they will not do so in such a manner as to resist the constant pressure from above of a hernial wedge. What propriety is there in suturing the lower end of a canal, the upper portion of which still offers the conditions requisite for hernia? Other surgeons pass the finger up the canal and trust to a more active reparative formation following the breaking up of the connective tissue to close the canal firmly. Others, again, pass sutures from one side of the canal across to the other, endeavoring in this manner to narrow the inguinal canal. Macewen not only "freshens the canal by the finger and the handle of the scalpel," but afterward, by means of carefully adjusted subcutaneous sutures, endeavors "to carry the conjoint tendon outward toward the fixed, unyielding ligament of Poupart, and to unite it with the transversalis and internal oblique muscles." It is safe to say, I think, that no such union will ever take place when the operation is done as described. No really fresh or raw surfaces are brought together, and as the overlying tissues are afterward sewed and the whole wound covered with an antiseptic dressing, these sutures are purely subcutaneous ones and useless. One might as well subcutaneously sew together the edges of the pectoralis major and the latissimus dorsi in the axilla and expect them firmly to unite. If the lax and stretched conjoint tendon is to be utilized in this manner to restore the so-called "valve" action, then a portion of its *length* must be removed, and so its lower edge brought back to the natural position.

If these sutures were passed, as described by Macewen, and then the superficial wound left open to heal by granulation, there would be some certainty of obtaining union between the edges of the transversalis and oblique muscles and Poupart's ligament. Even if such union were obtained there would still remain a short space filled with loose connective tissue between the peritoneum opposite the internal ring above, and the edge of the conjoined tendon below. That is, the backing to the peritoneum at the point where hernia begins would be imperfect. The only certain method of obtaining complete closure of the whole inguinal canal, excepting that portion occupied by the cord, is, I am forced to believe, the open treatment of the wound. And even this method is not entirely simple. If the wound is merely left open, that is, unstitched, the œdema of the loose tissue in the canal, and the strong tendency of the deeper parts of the wound to come together, will suffice to prevent the formation of any but a shallow and superficial cicatrix. To insure the formation of dense cicatricial tissue throughout the whole length and depth of the canal the wound must be carefully packed with some dressing down to the very bottom, that is, down to the transversalis fascia in the lower, and to the peritoneum in the upper part of the canal. When this is done œdema of the loose tissue of the cord will not occur, and granulations will cover the bottom and sides of the wound throughout its whole length with absolute certainty. An objection to placing any reliance upon cicatricial tissue, which I have heard raised several times is this, that cicatricial tissue "melts away," that in time it "yields," that "of course" it cannot be as strong as clean primary union. Nevertheless, cicatricial tissue has done great harm and great good often, and that by reason of its strength. Deep cicatrices which involve the

[1] Deutsche Med. Wochenschrift, Berlin, 1877, pp. 449, 467.

whole thickness of the skin and which form by granulation are extremely powerful. How often do we see the deep cicatrices of burns and other traumatisms of depth melt away? The umbilicus is a cicatrix, and one formed under the unfavorable conditions of constant motion and absence of support, and yet, when well formed, it is capable of bearing a great many insults from within. I have also heard the argument used against cicatricial tissue

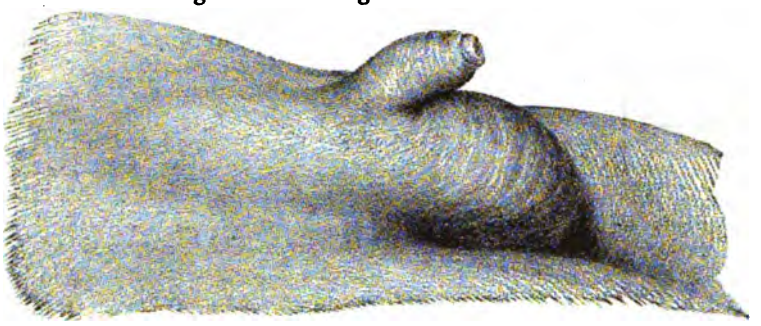

Fig. 1.

that it does not prevent a frequent occurrence of ventral hernia after laparotomies. The conditions, however, are very different after a laparotomy from those which exist after an operation for inguinal hernia. In a laparotomy all of the tissues of the abdominal wall are divided, including the transversalis fascia and the peritoneum. The union of the peritoneum and fascia must necessarily often be imperfect, and the intra-abdominal pressure is afterward brought to bear directly upon the cicatrix and upon any imperfection of surface.

After an operation for inguinal hernia the fascia transversalis lies uninjured behind part of the wound, and if the sac has been totally obliterated, a perfect peritoneal surface lies behind the whole of it. No invitation to direct pressure upon the cicatrix exists. It should be noted also that when, after any method of operating, a recurrence of the hernia occurs, this recurrence does not break down the whole posterior wall of the canal, but begins again at the internal ring, the very point where the original hernia began. This point, then, is the especial one—in fact, the only one—that particularly needs attention. I must refer to one method of treating the internal ring which is not infrequently mentioned as one of the steps in the operation. I refer to what is called "sewing-up" or "narrowing" the *internal* ring, with a view to preventing recurrence. When one remembers that the internal ring in inguinal hernia is a permanently dilated opening in the inelastic fascia transversalis, it is plain that stitches cannot

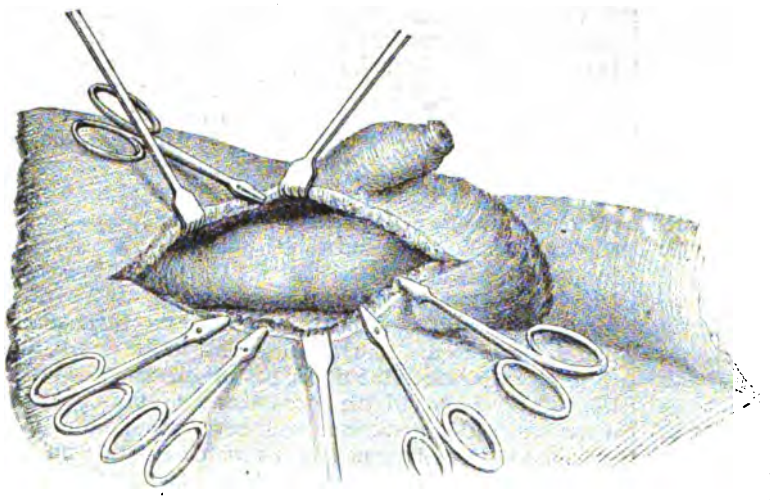

Fig. 2.

be applied to its edges so as to bring them together, for the edges of the ring are quite unyielding. The tubular prolongation of the fascia transversalis, from the edges of the ring down over the neck of the sac, might be tied off as the sac is, but the ring itself cannot be sewed up or narrowed by stitches. As a rule, there is a considerable quantity of loose areolar or fatty tissue at the extreme upper part of the neck of the sac, between the peritoneum and the fascia transversalis. It has seemed to me, therefore, safer to obtain granulation from the peritoneum itself outward than to first tie off the tubular prolongation of the fascia. I trust that I have not wearied you by allowing my remarks to take, so far, rather the line of argument than that of demonstration. This is, however, precisely the argument which I went through with in my own mind, and which led me to adopt the method of operating for radical cure in cases of inguinal hernia which I wish now to lay before you in detail. These illustrations will perhaps help to render the description more clear. The most careful antiseptic precautions having been adopted, especially in reference to cleansing the skin of the pubic, scrotal, and inguinal regions, a free incision is made, beginning a little *outside* the situation of the internal ring, and extending a sufficient distance downward over the sac. The incision is rapidly deepened over the whole length of the canal, so as to freely expose its anterior wall, that is, the aponeurosis of the external oblique muscle. The superficial layers over the sac are now cleared away (see Fig. 2) so as to

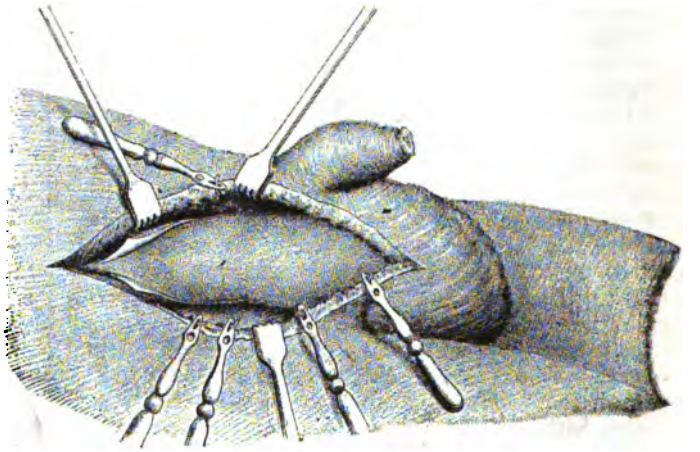

Fig. 3.

plainly show the whole anterior wall of the canal; the concave border of the external ring and its two pillars are completely exposed in their whole length. The sac is still covered below the external ring by the external spermatic or intercolumnar fascia. This fascia is now opened, and, one blade of a blunt scissors being pushed under the edge of the external ring, the anterior wall is split completely up to, and a trifle beyond, the outer border of the internal ring (see Fig. 3).

The deeper coverings of the sac are now dissected off, this dissection being often best and most rapidly accomplished with the fingers. If, now, the fascia transversalis is partially removed high up in the canal, it is quite easy to separate the spermatic cord from the sac, and this, too, often in congenital hernia. If begun below the external ring this separation is often extremely difficult. The cord being now separated from the sac up to a point a little within the abdomen, the whole sac is dissected out and lifted up (see Fig. 4.). In some cases, as in many congenital herniæ, this operation cannot be made, and then the sac must be cut away from the cord at each side of the latter. This illustration, like the others, is taken from the living subject, and serves to show that by this method the sac is completely exposed up to its very point of origin. At this stage, especially, the whole wound is thoroughly cleansed, and the hands of the oper-

ator and assistants washed. The sac is now invariably opened, and if intestinal contents are present these are reduced; if omentum is present it is very securely tied off with catgut, a large stump to prevent slipping of the ligature is left, and the rest cut away. The stump is pushed

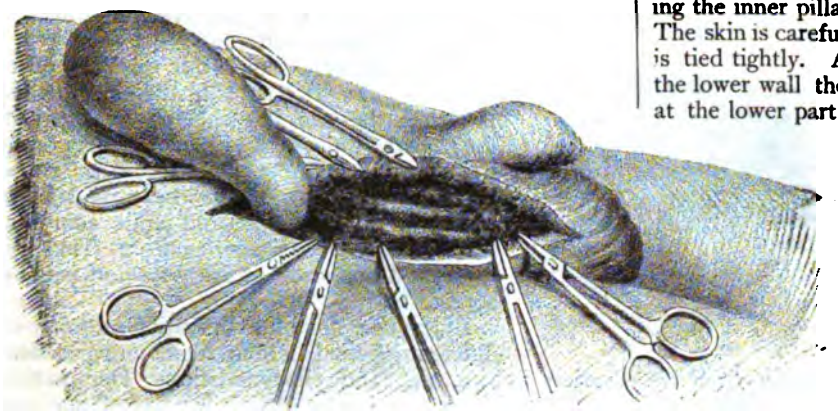

FIG. 4.

completely back into the cavity, adhesions being broken down or ligated if any are present.

The sac is now held up vertically from the internal ring (see Fig. 5), and the operator inserts one or two fingers through the neck and a little way into the peritoneal cavity. This is done to guard positively against the return of a piece of intestine or omentum into the sac during the application of the ligature. The first assistant then places the ligature of stout catgut or prepared silk about the neck at the very highest point, that is, on a level with the general peritoneum. The ligature is gently tightened on the operator's finger, and closed very tightly as the operator's finger is withdrawn. A pedicle, sufficient in size to prevent slipping of the ligature, is left, the rest of the sac being cut away. In congenital herniæ this step is a little more troublesome, as one must often resort to sewing the neck carefully and smoothly.

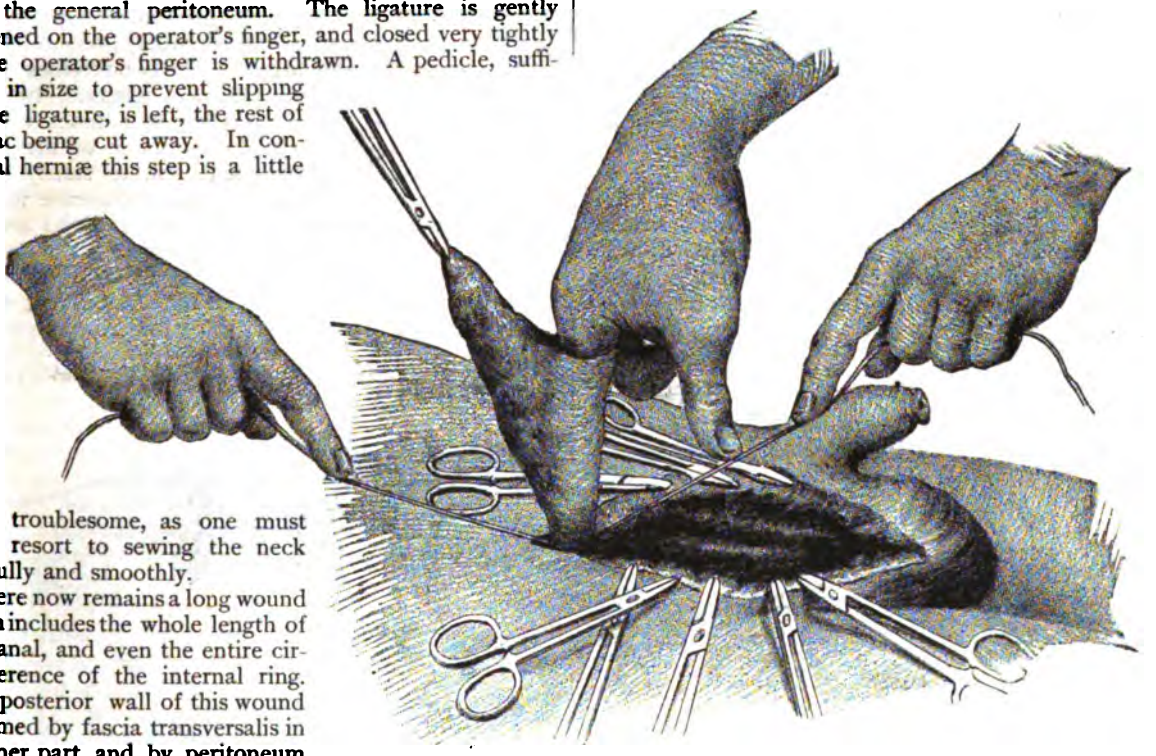

FIG. 5.

There now remains a long wound which includes the whole length of the canal, and even the entire circumference of the internal ring. The posterior wall of this wound is formed by fascia transversalis in its inner part, and by peritoneum in its outer part. The peritoneum on its inner surface is smooth, and the sac completely obliterated. The upper wall of the wound is formed by the edges of skin, superficial fascia, external oblique aponeurosis, and conjoined tendon; the lower wall by skin, superficial fascia, and a strip of aponeurosis, or, practically, Poupart's ligament, including the outer pillar. My aim being to insure the formation of granulation from the very bottom of the wound to the surface, it is not sufficient to simply pack the wound. The packing could easily become displaced, and the deeper layers rapidly but feebly unite. Moreover, it is desirable to bring down the stretched and lax edge of the conjoined tendon (see Fig. 6). These stitches of stout silk or catgut are therefore placed as follows: From four to eight, according to the size of the wound, bind together the tissues which form the upper wall of the wound, that is, the conjoined tendon, the aponeurosis of the external oblique (including the inner pillar of the external ring), and the skin. The skin is carefully and deeply inverted while each stitch is tied tightly. As many more sutures bind together at the lower wall the skin and Poupart's ligament, including at the lower part the outer pillar of the external ring (see Fig. 6). This suturing positively secures patency of the wound, and the formation of granulations from the bottom.

As thus arranged the wound would be unnecessarily wide, and now two or more heavy tension sutures are carried across the wound. These also relieve the tension on the edge stitches so that these latter do not cut their way out too soon (see Fig. 7). The application of the tension sutures is shown in this figure, the wound, when these are tied, being diminished to one-fifth or one-quarter of an inch in width. The tension sutures pass deeply through skin and superficial fascia, and are tied over pledgets of iodoform gauze to avoid ulceration. The wound is now carefully irrigated and dusted with iodoform throughout. Lastly, iodoform gauze is firmly packed through the entire length of the canal, particular care being necessary to see that, in packing at the outer angle, the whole circumference of the internal ring, including the stump of the sac, is covered by the packing. If this packing is not thoroughly done, the loose tissue in the canal becomes very œdematous in a few hours, and interferes with granulation formation.

The scrotal or labial wound is sewed up simply without packing, a drain being inserted at the lower end if necessary. This dressing is now covered with abundant masses of bichloride gauze and cotton, and the whole very firmly bound in place with bandages (see Fig. 8). Just beneath the bandage and surrounding the penis is placed a large square of thin rubber tissue, so that accidental soiling of the wound with urine may not occur. I have most of these patients empty the bladder through the catheter for some days after operation, in order to avoid soiling of the

dressing and too much motion of the parts. In children I have thus far always succeeded in keeping the wounds aseptic by enclosing the whole dressing, including the thigh, in plaster-of-Paris. A child so dressed cannot turn in bed, and may be placed, by the aid of cushions, so that

FIG. 6.

the stream of water is always directed away from the wound. In female children I thoroughly shellac the plaster as an additional precaution against urine. The dressing is not disturbed for five or six days, when, on removing it, the wound will be found to have begun to

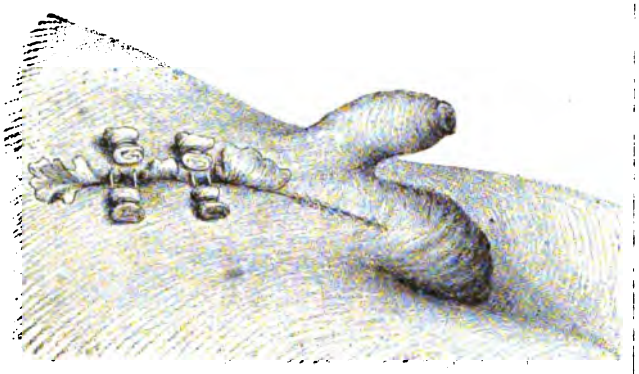

FIG. 7.

granulate. The packing is renewed in the same manner as at first placed, and changes are then made once in every four or six days. The time occupied in healing, so that a clean scar is formed, is usually from five to six weeks. The prone position for this length of time has seemed to me to be well spent; the scar becoming very strong (see Fig. 9). Certainly it is a small price to pay for the ability to get up from bed at the end of that time free from "the slavery of a truss," as one of my patients recently expressed it. None of my patients thus treated are allowed to wear a truss or support of any kind. If they were obliged to do that I should look upon the operation as very far from deserving the name of "radical cure." Moreover, I regard the constant pressure of a truss upon the scar as positively injurious to the strength of the latter.

The advantages claimed for this method of operating are: 1. That it is the only method in which the sac is completely obliterated. 2. That the walls of the canal are very firmly united, throughout its whole length, by strong cicatricial tissue. 3. That the wound being open the risk of abscess and septic complications is reduced to a minimum. 4. That it is rapid, and applicable to every form of inguinal hernia.

I have now done this operation on thirty-six different inguinal herniæ, representing a large variety in size, age, and characteristics. One patient died. This one was a man, fifty-eight years of age, and an old drinker. His wound did perfectly well, but ten days after operation he developed alcoholic delirium and died comatose eight days later. I should not have operated upon him until he had eliminated his alcohol more completely.

In three cases wounds became infected from diarrhœa, and were slow in healing, but in no case has any symptom suggesting general sepsis appeared.

In one case orchitis occurred and subsided readily.

In one case there was a relapse of hernia, easily accounted for by imperfection in operating, the cord not being separated from the sac sufficiently high up to allow the sac to be ligated at the level of the peritoneum. In no case has any symptom from pressure by the cicatrix upon the cord arisen. Thirty-one cases are reported upon up to date. One has relapsed, two cases cannot be traced; three cases are still under tretment. It may very properly be said that many of these cases have been too recently operated upon to satisfy anyone who requires the proof of time that recurrence may not occur. I think, however, that the patients who are here, and whom I shall ask you to inspect, illustrate satisfactorily that the principles involved in the operation are sound. I shall not occupy your time in reading to you the histories of the individual cases, but abstracts of these histories will be furnished with the printed report of this meeting.

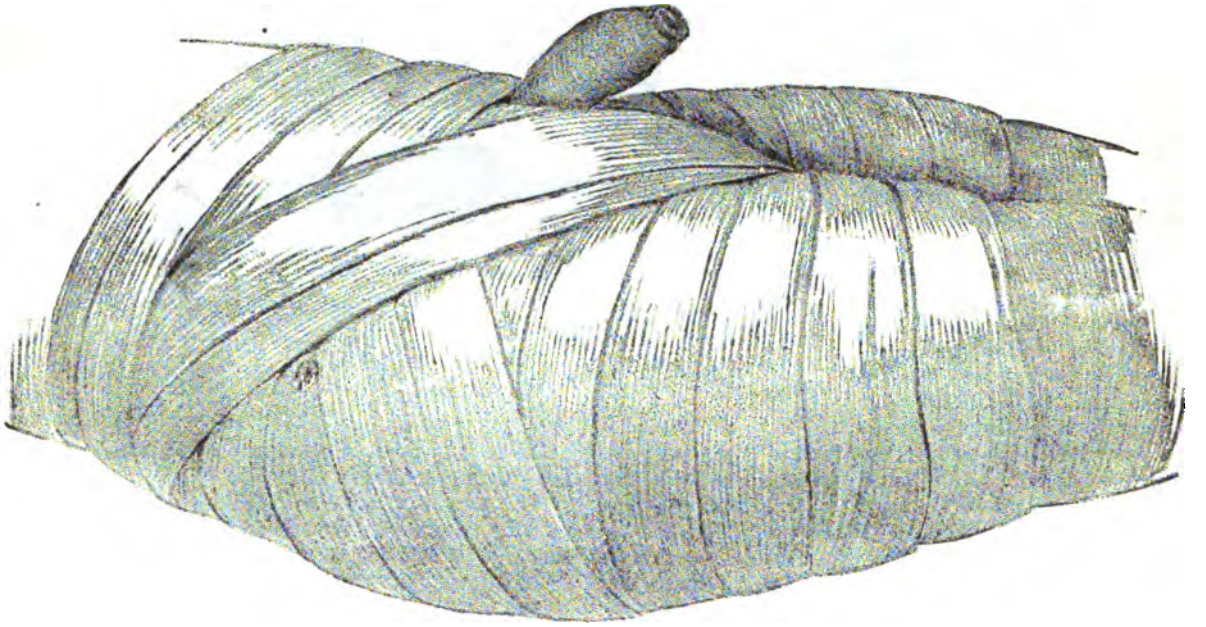

FIG. 8.

CASE I.—T. M——, aged fifty-eight, Ireland, in Roosevelt Hospital. Heavy drinker for twenty-five years

inguinal hernia, both sides; has worn a truss without success; operation, May 12, 1888; left side; does well; May 21, develops mild alcoholic delirium, and though no fever ever appears delirium continues, and patient died comatose on May 30th, eighteen days after operation.

CASE II.—William S——, aged sixty-six; double inguinal hernia since 1853. In May, 1887, was operated upon at

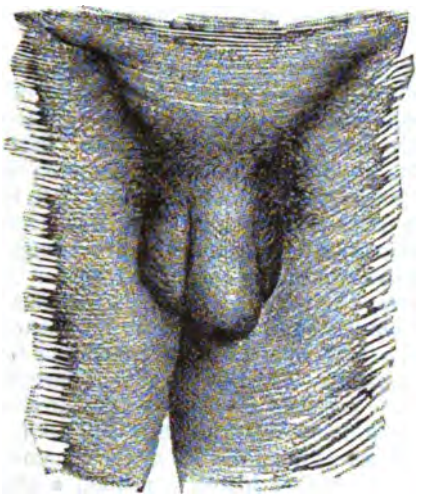

FIG. 9.

New York Hospital on both sides; at the end of two months both herniæ returned; left hernia large and cannot be held up by a truss; May 26, 1888, operation on left side; sigmoid flexure found to be prolapsed, and its uncovered wall to form part of wall of sac; July 4th, completely healed; not heard from since.

CASE III.—I. B——, aged sixty-one, colored; large scrotal hernia on right side, reducible; operation, June 1, 1888; remained in bed seven weeks; very slight superficial granulation left; patient now presented; very strong cicatrix.

CASE IV.—T. M——, aged forty-four; reducible double inguinal hernia, small; June 1, 1888, operation; soon had acute diarrhœa and right side become infected; slow in healing; six weeks in bed; seen recently; no recurrence.

CASE V.—H. B——, aged sixteen; rapidly increasing right scrotal hernia of four months' standing; operation, July 20, 1888; discharged cured, August 28th; seen within one week; perfect.

CASE VI.—H. W——, aged thirty; double scrotal hernia; one on right side of twenty years' standing, on left, eight months; double operation, July 27, 1888; August 31st, discharged cured; patient presented to-day perfectly sound. The last illustration was drawn from this patient.

CASE VII.—F. F——, aged three; right inguinal reducible hernia of one and a half year's standing; operation, August 24th; plaster splint; sent home, September 6th; patient presented to-day perfectly sound.

CASE VIII.—T. F——, aged twenty; right complete inguinal hernia and undescended testis; operation, August 17th; discharged cured, September 21st; seen this week; perfect.

CASE IX.—T. K——, aged thirty-two; left scrotal hernia of fourteen years; steady drinker; operation, August, 10, 1888; large mass of omentum excised; hernia congenital; separation of cord from sac very difficult and not carried as high as usual; alcoholic delirium; wound became infected and behaved badly, gaping widely as sutures cut out; discharged cured, October 1st; now a small recurrence, precisely like a small incomplete inguinal hernia; hernia follows track of cord as before; not the slightest yielding of lower portion of cicatrix.

CASE X.—T. L——, aged fifty-one; right inguinal hernia for twenty-nine years; left, for twenty years; operation, July 6, 1888, on right side; discharged cured, August 11th; patient presented to-day to Society; condition perfect.

CASE XI.—T. L——; operation, October 20, 1888; left inguinal; discharged cured, November 26th; patient presented to Society to-day; condition perfect.

CASE XII.—C. W——, aged twelve; right inguinal hernia; operation, October 27, 1888; contents, mass of omentum size of hen's egg; December 6th, complete healing; condition at this date perfect.

CASE XIII.—G. H. T——, aged forty-seven; very large left inguinal hernia, much inflamed and irreducible; twenty years' standing; operation, November 10, 1888; contents fluid, and large mass of omentum; internal ring two inches in diameter; omentum ligatured and cut away; discharged cured, December 23d; patient presented to Society to-day; condition perfect.

CASE XIV.—R. E——, aged thirty-seven; large left inguinal hernia of ten years' standing, irreducible; had had much discomfort and numerous attacks of strangulation; contents, omentum; operation, November 15, 1888; discharged cured, December 19th; condition now perfect.

CASE XV.—A. O——, aged twenty-seven; double inguinal hernia, results of straining from chronic cystitis; right hernia existed eight years; left one, six years; double operation, November 24, 1888; January 20th, healed; at present date perfect.

CASE XVI.—C. H——; right inguinal hernia, reducible; operation, December 15th; discharged cured, January 19, 1889; at present date perfect.

CASE XVII.—A. G——, aged five years ten months; right inguinal labial hernia; operation, January 12, 1889; contents, omentum; tied and removed; double spica plaster-of-Paris; February 15th, completely healed.

CASE XVIII.—B. W——, aged fifty-three; very large tubercular testis on right side; inguinal hernia with neck two inches in diameter above it; operation, November 10, 1888; testis removed and radical cure for hernia done at same time; January 10, 1889, patient discharged; hernia perfectly cured; sinus from tubercular cord remains; patient presented to Society to-day.

CASE XIX.—H. T——, aged sixty-three; right scrotal hernia of twenty-five years' standing, also hydrocele same side; operation, November 30, 1888; Volkmann's operation for hydrocele, and hernia also operated upon; discharged cured, January 7, 1889; at date perfect.

CASE XX.—F. M——, aged twenty-three; double inguinal hernia and retained testis on both sides; operation, July 28, 1889, right side; testis brought down to scrotum as far as possible and stitched; hernia operated for radical cure; August 31st, discharged; at date perfect.

CASE XXI.—F. M——. Operation, December 22, 1888; left inguinal hernia and undescended testis; same operation as before; testis brought down and hernia operated on; discharged cured, January 16th; at date perfect.

CASE XXII.—P. H——, aged forty-three; large right inguinal hernia, reducible; operation, December 1, 1887; wound healed, January 2, 1888; at present date perfect.

CASE XXIII.—F. McG——, aged twenty-three; left inguinal scrotal hernia, reducible; operation, January 26, 1888; wound healed, March 2d; patient seen to-day; condition perfect.

CASE XXIV.—O. L——, aged twenty-three; left inguinal omental hernia; operation, March 30, 1887; congenital sac full of adherent omentum; omentum tied off. May 18th, wound soundly healed; at present date perfect.

CASE XXV.—S. K——, aged seventeen; inguinal hernia and retained testis; operation, May 8, 1887; radical cure; operation, and testis removed; soundly healed at six weeks; at present date perfect.

CASE XXVI.—M. P——, aged twenty-four; right inguinal hernia, five years' standing; operation, April 23, 1887; contents, adherent omentum; wound soundly healed, May 27th; at present date perfect; patient presented to Society to-day.

CASE XXVII.—F. J——, aged thirty-nine; small right omental hernia; operation, May 21, 1887; sound healing in seven weeks; at present date perfect.

CASE XXVIII.—H. T——, aged thirty-two; large left inguinal hernia, three years' standing; operation, February 7, 1887; sac congenital and empty; wound soundly healed, April 4th; patient seen about three months ago and condition found perfect.

CASE XXIX.—R. M——, female, aged sixteen; right inguinal hernia of nine years' standing; operation, December 28, 1886; wound completely healed, February 3, 1887; at present date perfect.

CASE XXX.—A. N——, female, aged twenty-eight; right inguinal hernia, irreducible, fourteen years' standing; operation, May 7, 1887; ovary found in right labium; wound healed on June 15th; just reported at present date perfect.

CASE XXXI.—J. G——, aged forty; left indirect inguinal hernia which filled the scrotum; hernia had existed twenty-five years; operation, October 21, 1887; wound healed in seven weeks; patient presented to Society to-day; condition perfect.

ON THE USE OF TOBACCO.

BY FRANCKE H. BOSWORTH, M.D.,

NEW YORK.

IN one of Columbus' earlier voyages of discovery his men, returning from the exploration of one of the smaller West India islands, reported that they had seen the natives holding firebrands in their mouths, the smoke of which was permitted to escape through the mouth, nose, and ears. A closer inspection discovered their mistake, and for the first time made Europeans acquainted with the pleasures and delights of the use of tobacco. Its adoption and introduction among the people at home followed, and but a few years elapsed before its use became common among all civilized nations. Like all new ideas, its introduction met with opposition, and its use was interdicted by law, and forbidden by papal anathemas and clerical exhortation. Royal edicts were promulgated against it, and numberless tracts published setting forth its dangers; James I., among others, publishing his well-known tract setting forth the evils of the use of the "pernicious weed." His teaching has been forgotten, but it is interesting to record that the name which he gave it survives to this day, only we call it the "fragrant" weed and not the "pernicious weed." Notwithstanding all this opposition the use of tobacco has increased and extended, until to-day it is probably used by every people on the face of the globe, constituting the one single universal article of commerce, in that it not only figures prominently in the commercial statistics of every civilized nation of the world, but is sold to, or cultivated by, all peoples, whether civilized or uncivilized. It is probably a well-authenticated fact that the aborigines of America were the one people on the face of the globe who had not discovered a method of preparing an intoxicating beverage, and who were not addicted to the use of alcohol. It is a somewhat curious fact, then, that the most notable gift which civilized Europe received from America was tobacco, while its most notable gift in exchange was alcohol. The commentary is scarcely necessary that it was not the civilized world that suffered by the bargain. The crusade against tobacco which was inaugurated upon its first introduction to civilization continues to the present day, and it becomes a matter of some interest to inquire, in all candor, how far the charges made against its use are to be accepted. Burton, who was by far the best read man, and one of the shrewdest of his day, writing three hundred years ago, in the "Anatomy of Melancholy," sums up in his quaint way as follows: "Tobacco—divine, rare, superexcellent tobacco, which goes far beyond all their panaceas, potable gold, and philosopher's stones. A sovereign remedy to all diseases. A good vomit, I confess, a virtuous herb if it be well qualified, opportunely taken, and medicinally used, but as it is commonly abused by most men, which take it as tinkers do ale, 'tis a plague, a mischief, a violent purger of goods, lands, health. Hellish, devilish, and damned tobacco, the ruin and overthrow of body and soul."

Making all allowances for his exaggerations and pessimistic habit of mind, is there not something of suggestion in this quotation, and are we not in some danger of falling into the routine habit of condemning the use of tobacco and ignoring the difference between its use and abuse? Carlyle, in his "Reminiscences," tells how he once rode sixty miles to Edinburgh "to consult a doctor, having at last reduced my complexities to a single question. Is this disease curable by medicine? or is it chronic, incurable except by regimen, if even so? This question I earnestly put; got response: 'It is all tobacco, sir, give up tobacco.' Gave it instantly and strictly up. Found, after long months, that I might as well have ridden sixty miles in the opposite direction and poured my sorrows into the long, hairy ear of the first jackass I came upon, as into this select medical man's, whose name I will not mention." Carlyle evidently consulted a more devoted disciple of Father Trask than of Æsculapius.

A few days ago I noticed, in one of our daily papers, a certain action taken by a prominent religious body in one of our Western States which was something as follows: "Whereas, the use of tobacco in any shape or form is a filthy, pernicious, and degrading habit, imperilling the health of the body and the welfare of the soul alike, leading to a laxity in living which is the sure road to intemperance and all vice," etc., etc.; "Therefore, it is resolved that this conference will not grant ordination or license to preach to any candidate who is a victim to this debasing habit." In the London *Lancet* of a few months ago I recall an opinion which it was almost refreshing to read, for the mere courage which enabled the writer to make so bold an assertion. I only remember now the general tend of the article, which was that, as far as the writer's observation served him, he failed to see that the use of tobacco either shortened life or impaired the health of the average man, but, on the contrary, it was an open question, bearing in mind its well-known action as a nerve-sedative, whether, on the whole, its use might not be beneficial in quieting the overwrought nervous system, soothing a brain overtaxed by the cares and anxieties attendant upon an active, busy life. It is mainly with reference to a few of the questions suggested by the above that the brief paper I have to offer to-night has been prepared.

The Anglo-Saxon races have been smoking and chewing now for nearly four hundred years. They contracted the habit from a race which, as far as history and tradition teach us, were remarkable for their vigor of body and mind as well, and, as far as we know, were an unusually long-lived people. In the time that we have been using the weed there is no evidence to show that the race has in any way deteriorated, but, on the contrary, it is abundantly shown that the average duration of life has increased nearly fifty per cent. There is no evidence to show that in this time the race has been more subject to disease, but rather that they are less so. There is no evidence to show that the race has lost anything in its intellectual activity, but, on the contrary, it has been a time of most marvellous fecundity in all that is great in literature. Let us look more especially at the specific action of tobacco. It is used in smoking, chewing, in snuff, and in dipping. As far as its specific action is concerned, we are only interested in the two methods of its use—in smoking and chewing. The usual analysis of tobacco now accepted is that of Posselt and Reinmann, which is as follows:

Analysis of the Leaf.

Nicotine	0.060
Volatile oil	0.010
Bitter extractive matter	2.870
Gum and malate of lime	1.740
Chlorophyl	0.267
Albumen and gluten	1.308
Malic acid	0.510
Salts of pot. cin. and ammonia	0.734
Silica	0.088
Water	88.280
	100.00

Leaving out from this analysis the volatile oil, extractive matter, albumen, gluten, and chlorophyl, and negative and inert matter, and we have left a substance containing 1 part of nicotine, 4 parts of salts of lime, ammonia, etc., with 88 parts of water in 100. It is interesting to note, in this connection, that the percentage of nicotine in various kinds of tobacco varies, and that Havana tobacco contains but two per cent. of this poisonous element while Virginia tobacco contains about seven per cent., according to some analyses. The moral of this is that we should always smoke the choicest brands of Havana cigars. In smoking, the ammonia salt may become the source of considerable discomfort in the burning and smarting tongue which results from excessive and continuous practice of the habit; of course, in chewing this action is not noticeable. We thus are reduced to the action of nicotine for the possible deleterious influence of the plant. This element, as before stated, is present in varying proportions in the tobacco-leaf; according to some writers, from one to seven per cent. It is a clear and colorless fluid, highly volatile, and of an extremely pungent, disagreeable odor and strong, burning taste. It is rapidly absorbed into the fluids of the body, and is one of the most deadly poisons known. It is rendered volatile by burning the leaf and is present in the smoke of the tobacco. It is generally accepted that the volatilized nicotine in the tobacco-smoke is more actively absorbed than is the case when the leaf is chewed, but in either case the nicotine absorption is the essential element in the production of all of the evils which can be charged to the habit. Nicotine acts on the heart, nervous system, stomach, and upper air-passages. The prominent symptoms which may be caused by nicotine, with reference to the heart, are intermission and palpitation; that is, it produces certain functional disturbances of the heart which, for the time, may be the source of more or less discomfort to the patient; but the important point is, does this condition ever lead to one of organic lesion? I find but one writer bold enough to say that this occurs, and he only hazards the opinion (Dr. Kennedy, of Dublin) that the functional disorder may in cases eventually lead to the development of fatty changes in the muscular structure of the heart. On the other hand, there is abundant evidence to show that this is an extremely rare event. Few of us but have met with what we call a smoker's heart, one characterized prominently by the intermittent beat with some little irregularity of action and with which there may be the clinical history of occasional attacks of moderate palpitation brought on by overexertion. We keep these cases under notice, it may be for years, and we rarely, if ever, discover, anything that we can call an unfavorable progress, the development of any new symptom or any evidence of weakness of the muscular structure of the heart. I confess that this is not easily to be explained. I am disposed to regard the term functional disorder as merely a cloak to conceal our ignorance of the real pathological condition, and believe that there is really a structural change of some kind which escapes our present methods of exploration, and, while such imperfection exists in our means of physical diagnosis, we must continue to use the term functional disease. Still, in the case in point, whatever be the cause or explanation, we have a purely functional derangement which may exist for months or years without the occurrence of any grave or serious complication to cause apprehension. The true explanation of the action of nicotine on the heart is probably to be found in its action on the general nervous system, and especially on the pneumogastric nerve. In acute nicotine-poisoning, death has been known to take place in thirty seconds. This can only be explained by its action on the nervous system. Of course, the prominent symptoms of acute poisoning are on the circulatory and respiratory movements. It arrests respiration or markedly interferes with it, and if sufficient of the drug has been given it arrests the heart's action, producing almost instant death. We may, of course, say this is due to its immediate action on the medulla, or to its action on the pneumogastric nerve. Certainly, there is abundant clinical evidence to show an especial affinity of the drug for this nerve, whether in cases of mild or severe poisoning, as in acute or chronic cases. We may, then, sum up its action on the nervous system in producing disturbance of vision, giddiness, muscular tremors with exhaustion, sleeplessness, and depression of spirits. In addition to these, the irregularity of the heart's action may be classed as a nerve-symptom, dependent on the impairment of control which the pneumogastric nerve exercises over it. Another organ prominently affected by the tobacco-habit is the stomach, giving raise to a gastric catarrah, with its usual train of symptoms, gastralgia, acidity, nausea, anorexia, etc., and which it is, of course, unnecessary to describe. The idea that this is due to the local irritant action of the nicotine or of the saline constituents of the tobacco is not to be entertained. For although, occasionally, we meet with a tobacco chewer who swallows the saliva impregnated with the tobacco-juice, he possesses happily a very rare and unusual organization who can do this with impunity. The nicotine action, then, on the stomach must also be explained by its paretic action on the pneumogastric nerve. In this case we have to do with a secreting organ whose healthy functional activity depends largely on the nerve-force supplied by this nerve. If now the nerve is under the influence of this powerful narcotic, the organ, when called upon for the performance of its normal digestive function, is found unequal to the task, and the ingesta act as a local irritant with the result of producing a local catarrh, and each subsequent demand upon it only serves to aggravate the existing condition.

Coming, now, to the upper air-passages, we find here a portion of the body which is not a glandular structure or a secreting organ *per se*, and hence one which is not liable to such impairment or perversion of function as may react in any way on the general system. It is merely a passage lined with mucous membrane through which the inspired air carries oxygen to the air-cells. Now the use of tobacco may affect this either by direct contact or it may affect it indirectly through the effect of the nicotine on the general system. Its action through the general system can be but limited, as its effect here would be simply in diminishing secretion. We must look, therefore, for its injurious effect upon the direct contact of the smoke with the mucous membrane. Now, in those in the habit of smoking, the fumes of the tobacco come in contact with the upper air-passages ordinarily in but a limited extent. In fact, of two persons in a room whose atmosphere is surcharged with tobacco-smoke, one smoking and the other not accustomed to the habit, it is the non-smoker who will suffer. Furthermore, if we examine the physical characters of tobacco-smoke more carefully, we find its analysis is as follows: Nicotianin, carbonate of ammonia, acetate of ammonia, empyreumatic oil, carbonaceous matter, moisture, and several juices.

Passing over these latter as merely the result of the destruction of the woody fibre, we have again the salts of ammonia and the nicotine comprising the essential elements of the tobacco-smoke. So that, whether smoked or chewed, we find the active elements of possible influence of the plant in the nicotine and the saline constituents. The saline elements need but a passing word.

They are in a high state of solution and their action is but feeble. Absorbed by the mucous membrane, their action is nothing. Their local action on the mucous membrane of the mouth and throat is merely as a feeble stimulant and irritant. If their action be long continued this irritation may become quite prominent. This we have all noticed who have been addicted to something more than moderate smoking.

It is a fair inference, I think, then, that the use of tobacco, in its influence on the respiratory tract, does not directly produce the morbid condition which it is usual to charge upon it by direct action, but that it is only through the indirect influence of the nicotine absorption through the general nervous system. Now, the evidences of chronic nicotine-poisoning are well known and easily recognized by the muscular tremor or unsteady hand, the dull headache, the retarded or irregular heart-action, the sleeplessness, and other symptoms; and unless we have some evidence, as shown by some of these symptoms in persons addicted to smoking or chewing, of this chronic poisoning, I do not think that we are justified in attributing the existence of a pharyngeal or nasal catarrh to the use of tobacco, although undoubtedly, in many cases, an existing catarrhal condition of the fauces may be aggravated by the use of tobacco, its action being possibly the slightly irritating effect of the volatilized saline constituents of the smoke and possibly the empyreumatic oils, but mainly, I take it, through the constitutional effect of the drug as acting upon the secretions through the nerves which regulate this function.

While, therefore, by no means advocating the use of tobacco, the point which I desire to make is: Are we not often liable to fall into a mistake in universally condemning its use without sufficient grounds, and is it not better when our advice, as physicians, is asked, in this respect, to base our answers entirely on the evidences of the effect of the drug upon each individual patient and, furthermore, to recognize the fact that this effect is shown by well-marked and easily recognized subjective symptoms? I have frequently, when asked this question, "Does smoking hurt me?" frankly said to my patients, "You know better than I do; no man uses tobacco to his harm without being fully conscious of it."

As regards its effect on the diseases of the upper air-passages, in a practice of twenty years largely devoted to treatment of these affections, I recall but exceedingly few cases wherein I have found it necessary to interdict the use of tobacco as injuriously affecting, in any way, these passages, or as interfering with the success of treatment.

The object of my paper, then, is not a plea for the use of tobacco, but simply to suggest whether we had not best abandon the idea that it is a drug whose use is pernicious in every way to body, mind, and morals, and rather to take the view that it is one of God's good gifts to man; a "virtuous herb, divine, rare, superexcellent tobacco" when properly used, but when taken "as tinkers do ale, 'tis hellish, devilish and damned tobacco."

THE FUNCTIONS OF THE AMNION.—Dr. Cane believes (*The Lancet*) that the chief primary function of the amnion is to support and assist in moulding the embryo by muscular contraction. Its next function is to secrete the liquor amnii. The first use of this fluid is to afford equal pressure and support on all sides to an embryo growing by blood-pressure, developed and modified by muscular action. The next essential use of the liqour amnii is to convey oxygen for the purpose of keeping the embryo alive until the time when the new being obtains another means of getting that oxygen for its system. Following these primary essential functions come all those enumerated in the various text-books. Fishes and amphibians have no need of an amnion and amniotic fluid, because the sea and the rivers and the lakes are their amniotic cavities and liquor.

TRAUMATIC ABSCESS OF THE LEFT ANTERIOR AND PARIETAL LOBES OF THE BRAIN, FROM A FRAGMENT OF AN EXPLODED ARMY-RIFLE METALLIC SHELL.

BY L. MERVIN MAUS, M.D.,

CAPTAIN AND ASSISTANT SURGEON, UNITED STATES ARMY.

THE following interesting case, occurring in my practice at Fort Lewis, Col., in 1883, possesses sufficient interest, in my opinion, to warrant publication, especially as the localization of brain injury and disease is attracting very considerable attention from the profession at the present day. Sergeant Alpheus Ryan, Company K, Twenty-second Infantry, aged twenty-six, native of Virginia, while engaged in reloading cartridges, about 6 P.M., June 9, 1883, was accidentally injured by the explosion of a brass rifle-shell, calibre 45, a fragment of which entered his face about one centimetre from the left corner of his mouth, causing unconsciousness and a copious hemorrhage from the external wound. The sergeant was taken immediately to the post hospital, where, upon examination, it was ascertained that the fragment had passed through the cheek, inflicting an injury to the superior coronary artery and appearing in the buccal cavity opposite the left upper second molar, from which it disappeared into the muscular tissue of the cheek. The external and internal wounds were so slight as to be scarcely noticeable; the hemorrhage, which was very profuse, was temporarily controlled by pressure of the facial artery, and finally by means of the persulphate of iron. The patient remained unconscious and in a collapsed condition, with stertorous breathing, during the entire night, face blanched and livid, pulse weak and thready, ranging from fifty to sixty per minute, notwithstanding repeated enemata of brandy and carbonate of ammonia. During the night and following day the patient remained partially unconscious and in a comatose condition, until June 11th, or about forty-eight hours after the accident. A careful examination was made in the buccal cavity, in order to determine the locality of the shell fragment, on the morning of the 10th, and from the marked depression of heart's action, together with the comatose condition of the patient, a conclusion was drawn that the fragment had by some means found its way into the brain. On the afternoon of the 11th the patient regained consciousness and was able to answer questions.

He was free from pain, temperature about normal, pulse sixty, and no disturbance of the motor or sensory nerve system. The mind became perfectly clear; could express himself well; no aphasia, and a gradual improvement in general condition except the heart's action, which persistently remained at sixty or less. On the 13th of June he was out of bed, feeling well, with good appetite, and was allowed to walk around the ward. From this date until the 23d improvement was gradual, and the patient was permitted to go to his company quarters occasionally, and to saunter around the garrison. The case was watched with much interest, as I felt quite satisfied that the trifling piece of shell had embedded itself somewhere in the cortex of the brain. There was nothing of especial interest at this time to note among the symptoms except the reduced number of heart-beats per minute, which continued at sixty. He complained of nothing, nor could I detect any sensory or motor disturbances. His treatment consisted of digitalis and ferruginous tonics, together with a generous diet.

June 23d.—Patient passed a comfortable night, felt unusually well at 7 A.M., and ate well at breakfast. At 10 A.M. he became nauseated and vomited several times. Nausea continued in afternoon, and one-drop doses of Fowler's solution given every half-hour; at 3 P.M., patient slightly delirious and feverish, vomiting and nausea continued; bromide of potassium and chloral hydrate were given at bedtime, and patient slept tolerably well during the latter part of the night. It is fair to suppose that the

delirium and fever which occurred during the night of the 23d inst., was the initial point of the cerebral abscess; the fragment of shell which had remained embedded until up to this time had probably been non-irritating.

June 24th.—Patient still delirious, occasionally vomiting; delirium mild in character; desired to go to duty. At 10 A.M. pulse was 60, and temperature 102° F.; iced wine was given during day. At 9 P.M. pulse was 83; temperature, 102.5° F.; paralysis of bladder occurred during the day.

June 25th.—Patient slept several hours during the night, under the influence of chloral and bromide of potassium; conditions about the same. At 10 A.M., pulse, 70; temperature, 102.5° F. The depression of the heart's action remained during the entire sickness as a prominent symptom.

The patient suffered no pain, and invariably replied, when asked how he felt, "Very well, sir." A disinclination to lift the head from the pillow was observed, and it was generally kept on the left side. Pulse, at 9 A.M., 81; temperature, 103° F.

June 26th.—No especial change noted; general apathetic condition existed. 7 A.M., pulse, 84; temperature, 103.8° F. 7 P.M., pulse, 91; temperature, 103.8° F. The body was sponged with diluted alcohol.

June 27th.—Patient passed a restless night; in the morning was in a semi stupor. At 7 A.M., pulse, 145; temperature, 104.5° F.; was placed in cold baths, during the day, every two hours, the ordinary bath-tub being used; water at 98° F. temperature, and reduced to 88°, patient remaining in bath ten minutes at time. At 7 P.M., pulse, 104; temperature, 101.4° F.

June 28th.—Patient's mental condition remained about the same. 7 A.M., pulse, 114; temperature, 102.6° F.; skin moist; tongue tolerably clean. Baths continued at intervals during the day; urine passes involuntarily; bowels moved by enema. At 7 P.M., pulse, 96; temperature, 100.8° F.

June 29th.—Patient slept well; feels better, and looks brighter. 7 A.M., pulse, 99; temperature, 100.4° F.; slight pain noticeable in back of neck. At 7 P.M., pulse, 98; temperature, 100° F. Baths were now discontinued.

June 30th.—Condition of patient about the same. Pulse, 7 A.M., 99; temperature, 101° F.; profuse perspiration at times. 7 P.M., pulse, 101; temperature, 102.6° F.

July 1st.—Patient very feeble, desires to sleep continually; pupils normal and sensitive to light. At 7 A.M., pulse, 94; temperature, 102.6° F. Several baths were given during the day, and the temperature was reduced to 100.2° F. in afternoon.

July 2d.—Patient looks brighter, answers questions well, slight pain still in back of neck, takes nourishment and medicines well. At 7 A.M., pulse, 78; temperature, 100° F

From this date on to death there was a gradual weakening of the vital powers, with scarcely any recognizable change in the motor or sensory centres. The patient felt more inclined to sleep, and apparently was continually dozing. When aroused he would take nourishment and medication. From July 2d to July 10th very little change in condition, when the temperature suddenly reached 95° F. on the morning of that date. At 7 P.M., same day, pulse, 63; temperature, 98.4° F.

July 11th.—Patient passed a fair night, but restless; slept, or appeared to sleep, most of the time; this morning is not inclined to answer questions or speak. Forehead cool, face slightly flushed, eyes somewhat glassy, nervous twitching about fingers when spoken to, seems conscious, but gradually fades into an apathetic condition. Patient remained about the same until the morning of July 15th, when he regained consciousness and was inclined to talk; said he felt all right and had no pain; pulse was up to 140 at 7 P.M.; temperature, 101° F.

July 16th.—Patient this morning dull and stupid and hard to arouse; inclined the head to the left side on the pillow; the skin was relaxed with copious perspiration; legs and feet dry and cool, almost cold. He took considerable stimulants during the day, and remained in a stupid condition during the 17th, 18th, and 19th, with little change.

July 19th.—Passed a quiet night; this morning was very weak, and breathing stertorous in character; perspiration was free, left side was cold and clammy (arm and leg), right side fairly warm; took quantities of brandy and meat-juice during the day, but was evidently unconscious.

July 20th.—Remained in a stupor all night, breathing labored and stertorous, perspiring freely; pulse very rapid, 164 per minute; temperature, 102° F.; left side still cold and clammy. Patient was now unable to take nourishment by mouth; enemata were ordered. During the afternoon it was noticeable that he was rapidly sinking; and at 4 P.M., very quietly, still unconscious, death occurred.

Autopsy, eighteen hours after death. Dura and sinuses normal, veins of pia congested, brain soft; a round yellowish opening was observed at the anterior surface of the left frontal lobe, from which pus exuded; also at the anterior margin of the left parietal lobe, just behind the fissure of Sylvius. An incision made connecting these two openings exposed a large abscess extending through the entire frontal lobe, and occupying nearly the entire lobe. In the centre of the abscess was found the fragment of shell, weighing about three decigrams, almost quadrilateral in shape, and measuring on each side a little more than one centimetre. Upon examination of the inner tablet of the calvarium a small slit was discovered in the great wing of the sphenoid bone, on the left side, about one and a half centimetre behind the sphenoid fissure. It may be interesting in a surgical way to trace the course of the fragment, which was as follows: After striking the second left upper molar, it was deflected and passed back into the cheek, and followed the temporal muscle into the zygomatic fossa; thence perforating the skull through the thin wing of the sphenoid, it entered the anterior margin of the left parietal lobe, passing through the fissure of Sylvius, barely escaping the middle cerebral artery, and buried itself midway in the left frontal lobes.

FORT PORTER, N. Y., February 28, 1889.

ANATOMICAL AND PHYSIOLOGICAL MEMORANDA.—In each respiration an adult inhales one pint of air. Man respires sixteen to twenty times a minute, or twenty thousand times a day; a child, twenty-five to thirty-five times a minute. While standing the adult respiration is twenty-two; while lying, thirteen. The superficial surface of the lungs, *i.e.*, of their alveolar spaces, is two hundred square yards. The amount of air inspired in twenty-four hours is ten thousand litres (about ten thousand quarts). The amount of oxygen absorbed in twenty four hours is five hundred litres (744 grammes); and the amount of carbonic-acid gas expired in the same time, four hundred litres (911.5 grammes). Two-thirds of the oxygen absorbed in twenty-four hours is absorbed during the night-hours from 6 P.M. to 6 A.M. Three-fifths of the total CO_2 is thrown off in the daytime. The pulmonary surface gives off one hundred and fifty grammes of water daily in the state of vapor. An adult must have at least three hundred and sixty litres of air an hour. The heart sends through the lungs eight hundred litres of blood hourly and twenty thousand litres, or five thousand gallons, daily. The duration of inspiration is $\frac{5}{12}$, of expiration, $\frac{7}{12}$, of the whole respiratory act. During sleep inspiration occupies $\frac{1}{2}\frac{1}{3}$ of the respiratory period.

RUPTURE OF THE SMALL INTESTINE WITHOUT WOUND OF THE ABDOMINAL WALL.—Dr. C. André reports in the *Archives de Médecine et de Pharmacie Militaires* for December, 1888, a case of a cavalryman who was kicked in the abdomen by a horse. Examination of the abdomen showed no evidences of a contusion, but signs of peritonitis set in, and the man died the following day. Post-mortem examination showed a rupture of the small intestine with extravasation of fæces.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, March 23, 1889.

THE MODERN PRACTICE OF SURGERY.

IT is pleasant occasionally to turn from the consideration of the question, Is medicine a failure? to contemplate the undoubted advances which have been, and are daily being, made in the science and art of surgery. It may be that we are no better able to cure any of the so-called self-limited diseases, at the present day, than our predecessors were one hundred years ago, or even, as some pretend, with a show of reason perhaps, that we are less skilled in the art of therapeutics than were our forefathers; but our enlarged surgical powers even the most pessimistic cannot deny.

We need not recapitulate the many evidences of progress made in abdominal surgery, in plastic operations, or in antisepsis—the foundation of most of the advances made, for there is never a medical congress where there is not at least one oration devoted to the setting forth of the proofs of such progress. It seems, indeed, as if the surgeon were only too glad to parade his triumphs before his brother working in the apparently less fruitful field of medicinal therapeutics.

In a paper read before the Massachusetts Medical Society (*Boston Medical and Surgical Journal*, January 17, 1889), Dr. Otis K. Newell refers to this subject and points out some lessons which he thinks may be derived from a contemplation of the present status of the surgical art. The writer's opinion of surgery is a high one, as witness the following: "The knowledge of proper and successful wound-treatment, under the operation of a principle [antisepsis] which until the past twenty years had never before entered the history of surgery, has been already so developed that a fatal result in no case of premeditated operation should ever occur. If it does, it must either be due to some unforeseeable complication or to poor surgical judgment." But this great step in advance is not without its increased measure of responsibility for the surgeon, and the author holds, as a corollary of the statement just quoted, that whoever shall undertake to do surgery to-day must be, except in emergency, held responsible for a completely aseptic course of wound-healing and at least a successful immediate result.

But in order that this uniform success may be attained, and that the surgeon may with justice be held to a strict accountability for its attainment, it becomes necessary to draw the line between the physician and the surgeon more sharply. In these days of rapid intercommunication, when a discovery in any part of the world becomes almost at once the common property of all, it is impossible for one to keep himself fully abreast with all advances in medicine; hence, in order to pursue his work in full justice to himself and his clients, or with profit to his profession, the practitioner must become a special worker. While seeking to avert the danger of becoming a "one-idea man," by laying a broad and solid foundation of general medical knowledge, the surgeon must, Dr. Newell holds, devote his whole time and energy to his own branch alone, and no man, he adds, is to-day justified in undertaking operative medicine "unless he has had, and is continually having, special surgical experience."

We fear it will take some time to educate the profession up to the point of demanding that a surgeon, in the country at least, shall keep to surgery alone, holding himself as a mere consultant, with no clientèle of his own, and yet the signs are not wanting that such a change is beginning to be effected.

LUNACY LEGISLATION IN NEW YORK.

THE present Legislature is more than usually occupied with the subject of our lunacy laws.

A resolution has been introduced into the Senate providing for the appointment of six commissioners to revise the lunacy laws of the State.

A bill has been introduced into the House to establish a State Lunacy Commission, to take the place of the present single roving Commissioner.

Senator Pierce has introduced a bill the general purpose of which is, according to accounts given, to discontinue the practice, which has prevailed in this State since 1864, of confining insane persons charged with crime at the Auburn State Asylum for Insane Criminals.

Dr. Carlos F. Macdonald has appeared against the bill, and the State Commissioner of Lunacy, Dr. S. W. Smith has appeared for it. The measure has been tabled. The bill providing that the dependent insane be placed in State rather than county institutions is still before the Legislature. The bill originates with the State Charities Aid Association, and has the almost unanimous support of the medical profession, and of all those who have made a special study of the care of the insane. It is opposed by the county politicians, a prominent spokesman being keeper of one of the County Poor-houses.

The bill provides that the State shall be divided into districts by a Board, to be constituted of the President of the State Board of Charities, the State Commissioner in Lunacy, and the State Comptroller. After this Board shall have established the insane districts they are to file with the Secretary of State the boundaries of the same, and the number of pauper insane people within each. In each of these districts suitable buildings and accommodations are required to be erected, either on new sites or on the site of some asylum already in existence. To these asylums indigent and pauper insane are required to be sent for maintenance, instead of being retained in county asylums.

Among the arguments for the new law are the fact that the present county system implies the necessity of building an asylum in each county, which would make sixty in all. Under the State district system there would be no

need for more than ten asylums. This number would afford ample provision for the insane for the next fifty years. Under the county system there can be no uniformity of management or treatment, while under the State system every improvement in the care and treatment of the insane could be availed of for use throughout the State, every improvement known to any one of the ten asylums being made equally applicable to all the other asylums.

If the bill fails to become a law it will be another unpleasant commentary on the degrading influence of politics in the management of our public institutions.

A SUBSTITUTE FOR ANTIPYRIN.

PHYSICIANS will all be glad that antipyrin has found a rival which promises to supplant it, in a large measure at least. This rival is phenacetin. In an article on the phenacetins, by Professor Dujardin-Beaumetz, in the *British Medical Journal*, the chemical, physiological, and therapeutical properties of these compounds are discussed, and the following conclusions are reached:

1. In the phenacetins we have excellent antihyperthermic and analgesic remedies.

2. Of the three phenacetins, two only possess therapeutic properties, para- and ortho-acet-phenetidin.

3. The ortho-acet-phenetidin must be given in larger doses than the para-acet-phenetidin. The medium dose of the latter is from 1.5 gramme to 2 grammes per day.

4. These two salts seem to be devoid of toxic properties.

5. They are powerful antithermics and very active analgesics, which ought to be substituted for antipyrin for the following reasons: *a*. Because they are non-toxic. *b*. Because they act in doses one-half smaller. *c*. Because they are one-half cheaper. *d*. Because, finally, there is no monopoly in their manufacture.

"Chemically," says Professor Beaumetz, "the phenacetins are derived from phenol, and to obtain them these phenols are submitted to five operations—first, the nitration of the phenol, the separation of the nitrophenols thus formed, their ethylation, the reduction of the bodies so produced; and, finally, their acetylation. The general formula of the phenacetins is

$$C_6H_4 \begin{cases} OC_2H_5 \\ NH\,C_2H_3O \end{cases}$$

The para-acet-phenetidin occurs as a white crystalline powder, liquefying at 134° C., barely soluble in water, very slightly soluble in chloroform, insoluble in glycerine, acidulated water, hydrochlorate of ammonia, oils, and liquid vaseline.

The ortho-acet-phenetidin presents itself in the form of brilliant white scales, without odor or taste, and fusing at 75°; it also is very slightly soluble in water, either cold or hot. Chloroform dissolves it in considerable proportions, and one gramme is taken up by three grammes of alcohol of 90° strength.

Regarding the therapeutic properties of phenacetin, Professor Beaumetz adds: "While it is quite as powerful as antipyrin and acetanilid, it does not cause the pain in the stomach, or the scarlatiniform rash of the former; nor does it give rise to the cyanosis of the latter. However prolonged may be its administration—and we have given it for months in doses of 1 to 2 grammes per day—we have never observed any bad effect. We have used it for the relief of every form of pain (neuralgias, migraine, rheumatic pains, muscular rheumatism, acute articular rheumatism, the lightning pains of tabes, etc.) and always with the best results. Further, in cases of hysteria, and of hysterical or neurotaxic pains, phenacetin has seemed to produce better effects than the bromides; it calms the excitability of the nervous system, and in some obstinate cases of nervous insomnia it procured sleep. Phenacetin seems therefore to be not only an analgesic but a hypnotic.

In this city the price of phenacetin is still quite high.

THE QUESTION OF CRANIOTOMY.

IN an address recently delivered before the Washington Obstetrical Society, Dr. Samuel C. Busey puts forward a number of reasons to sustain the view that craniotomy is no longer a justifiable procedure under any circumstances.

Dr. Busey estimates that 6,880 lives are annually destroyed in this country alone by craniotomy. In place of performing this operation, the modified Cæsarean section, with its present mortality to mothers of 72.52 per cent. (in America forty-five per cent.), and to children of 90.84 per cent., or the Porro operation, are recommended.

The maternal mortality in craniotomy is 2 or 3 out of 100; in Cæsarean section (Dresden clinic), 11 or 12 out of 100 for the mothers, and 13 out of 100 children. In craniotomy the obstetrician loses 10.28 lives; in section he loses 21.6 lives.

The issue, then, resolves itself, says Dr. Busey, into the actual or relative value of 5 or 6 women as against 87 infants. Dr. Busey votes for the infants.

His views upon this subject are, however, we venture to say, far too radical; there is some weakness in his logic, his data are by no means complete, and much of his argument is pure sentimentalism.

The exact mortality from Cæsarean section, when done by general practitioners and non-experts, is not known; but it will be long before we may expect that every country doctor can do it skilfully. Meantime, even in the hands of skilled surgeons in this country, the mortality to mothers is forty-five per cent.! Hence it is really, in America, a question of 55 mature lives as against those of 100 fœtuses.

The modified Cæsarean operation has been eagerly adopted by obstetricians, but even now only 135 cases have been reported; whereas it has its application, we are told, to the 6,000 cases annually in which craniotomy is now performed.

Again, it may easily happen that in future successful pregnancies the uterus may rupture, as has happened in the old Cæsarean operation.

The anti-craniotomists are, further, not agreed among themselves as to whether the Porro operation, or laparo-elytrotomy, may not be the better measure. Mr. Tait says: "The operation of amputation of the pregnant uterus, I venture to predict, will revolutionize the obstetric art, and in two years we shall hear no more of craniotomy or eviscerations; for this new method will save more lives than these proceedings do, and it is far easier of performance. It is the easiest operation in ab-

dominal surgery, and every country practitioner ought to be able and always prepared to do it."

It may be a very easy thing to do a "Porro" in a well-equipped hospital; but most confinements occur under conditions not favorable to delicate surgical work. As for the operation itself, if the child extracted dies, the surgeon has made the mother barren, and cut off forever her chance of satisfying her maternal instinct or establishing a family.

We take it, however, that the most fallacious portion of Dr. Busey's argument is in his balancing 5 or 6 mothers against 87 fœtuses, or new-born infants. Of these 87, less than one-half will grow to maturity, and, when mature, five per cent. will belong to defective or dependent classes. This reduces the equation to 5 or 6 useful lives as against 40. But, according to American statistics, fifty-five per cent. of mothers die from Cæsarean section. Hence we have a question of 55 mature useful lives lost by section, as against the gain of 40 potential adults.

These figures give the other side of the case, and show that everything surgical has not quite the roseate look which the enthusiastic laparotomist now inclines to attach to it.

There can be no doubt that, in the present state of our science, craniotomy is at times not only justified, but an imperative duty. Perhaps the time may come when it can be dispensed with; and, at any rate, arguments like those of Dr. Busey will have the benefit of showing that craniotomy is not so often indicated as it used to be supposed.

COMPETITIVE EXAMINATIONS.

A FEW months ago quite a discussion arose over the appearance, in the *Nineteenth Century*, of a solemn protest against the methods of competitive examination imployed in modern schools and colleges. This protest was signed by four hundred and thirteen persons more or less eminent in politics, letters, and education. The note of condemnation thus sounded was quickly caught up by the daily press, and its sentiments were emphatically indorsed. It is the fashion just now to condemn our educational methods, and here was an opportunity not to be lost. The examination-system, we were told, caused cramming and the attendant mental and physical ills, destroyed the love of learning for its own sake, and produced a spasmodic and unhealthy effort in place of systematic and scholarly pursuit of knowledge.

The editor of *The Universal Review* has been at some pains to show the other side of this question. He finds that the signers of the protest were in many cases gentlemen not connected with education, and that the list contained very few persons actually engaged in practical pedagogic work.

Turning to this class, he found by inquiry that, among two hundred and eighty-two head-masters or principals of schools, two hundred and thirty-four favored the use of competitive examinations as essential adjuncts in education. The whole evidence among practical and successful educators was therefore in favor of this system.

The subject is of some interest to physicians, as is everything connected with education and training of the young. In medical education the tendency is now to increase the number of examinations, and the utility and necessity of them are, we believe, generally acknowledged. Perhaps the examination-method is not rightly applied in many cases. If so, it is because such examinations are made too infrequently, and are correspondingly more formidable. But there is no substitute yet put forward for examinations. They afford the chief test of merit, and are, if properly conducted, a fairly safe and sure test of progress.

THE ABORTIVE TREATMENT OF SPECIFIC FEVERS.

A LITTLE work has recently been written by Dr. C. R. Illingworth, of London, entitled "The Abortive Treatment of Specific Febrile Disorders by the Biniodide of Mercury." The contents of this brochure are hardly so pretentious as the title. Dr. Illingworth claims only that the drugs which he recommends are the most effective agents in treating the specific fevers. He does not waste time in laboring to prove any hypothesis, but contents himself with asserting that the disorders in question are caused by germs which, when acting virulently, make exhausting depredations upon the corpuscles of the blood. The treatment, therefore, indicated should be germicidal and hæmatinic.

The biniodide of mercury will answer every purpose as a germicide, while iron serves as a hæmatinic. Furthermore, since the abstraction of oxygen from the blood reduces also the amount of fibrin, making it more fluid, the use of ammonia, soda, and such medicaments as lessen the fibrin-forming power of the blood is contra-indicated.

While all the specific fibrin disorders, from whooping-cough to syphilis, may be treated by the biniodide, it is in scarlet fever, diphtheria, and measles that its action is here specially described.

The biniodide is given in the form of pills, powders and mixture.

The mixture for an adult is as follows:

℞. Sol. hydrarg. biniodid. (B. Ph.) .... ℥ j.
Potas. iodid. ..... ℥ ss.
Syr. et aq. menth. pip..... q.s. ad ℥ viij.
M. ℥ ss. q. 2, 3, or 4 h.

For a young child, from one-third to one-half of this quantity is given. The pills contain gr. $\frac{1}{16}$, gr. $\frac{1}{8}$, and gr. $\frac{1}{4}$, to be taken three times daily. For infants and young children the powders answer best, and they are made of the strength of gr. $\frac{1}{16}$, mixed with sugar, and taken three times daily.

In the treatment of mild cases of scarlet fever the patient is given gt. ss. to gt. j. of perchloride of iron, with gr. ij. of chlorate of potash, every two or three hours, and biniodide three times daily. When there is very great disturbance of the stomach, the acetate of ammonia, of salicylate of soda, may be added to the above for a time.

Local treatment is at the same time imperative. This consists in the application to the throat of a solution made as follows: Add ten minims of a 1 in 4 solution of potassic or sodic iodide to ℥ jss. of a 1 in 500 solution of the bichloride of mercury and sweeten to ℥ ij. with pure glycerine. This makes a red mixture, in which the biniodide forms a fine precipitate suspended in glycerine. In those cases in which the biniodide mixture is vomited, a combination of bismuth, carbolic, and hydrocyanic acids answers well, while the biniodide is given in powdered form.

In the malignant form of scarlet fever, Dr. Illingworth follows the usual practice. He increases the amount of iron in its astringent forms, adds alcoholic stimulants, and gives the biniodide as usual. He wisely advises against the use of antipyretics, such as antipyrin, antifebrin, or aconite.

The biniodide has also proved an efficient prophylactic.

The biniodide treatment of diphtheria is much the same as that for malignant scarlet fever. The same treatment is "signally efficacious" in whooping-cough.

The criticism which would be made of Dr. Illingworth's biniodide treatment is, that it is not a biniodide treatment at all, but might just as well be called the iron and potash treatment. How much of good effect comes from the germicide is a question very far from being settled by the evidence Dr. Illingworth gives us.

A FEW WORDS WITH OUR CORRESPONDENTS.

We have received recently several communications from our readers, upon various topics of a more or less personal nature, to which we will reply collectively, since it is impossible to answer each one by letter, and to state the reasons why the desired information cannot be furnished.

Some of these letters are from laymen, who give a detailed statement of their symptoms and ask for an opinion and advice. Others are a little more considerate, and furnish us with a ready-made diagnosis, asking only for a prescription suited to the individual case. Others, again, write requesting us to give them the name of the best oculist, or gynecologist, or genito-urinary surgeon, in the latter case usually taking the pains to state that the information is desired for a friend who has been unfortunate. Sometimes the correspondent says that he or she has been recommended to Dr. So-and-so, and asks for an opinion concerning that gentleman's professional attainments. It would appear unnecessary to say, were we not so constantly in receipt of communications of this sort, that THE MEDICAL RECORD is not designed to usurp the functions of the family physician, and it is to the latter that our correspondents must direct their inquiries.

But there is another class of correspondents, physicians, many of whose inquiries we would gladly answer did time and space permit, notwithstanding the fact that they are sometimes unreasonable in the demands that they make upon us. It is not unusual, for instance, to receive a letter from a physician who intends to read a paper before some medical society, in which he requests us to make out for him a complete bibliography upon the subject which he has chosen for his theme, or even to furnish abstracts of the most important articles. A little reflection ought to be sufficient to convince anyone that it would be out of the question to comply with such a request. It is furthermore unnecessary, since a letter addressed to the librarian of the Surgeon-General's office at Washington will bring the desired information upon payment of a very moderate fee.

Another subject upon which we are not infrequently asked to advise our readers is concerning the reliability of advertisers in THE MEDICAL RECORD, or as to the relative merits of two or more houses dealing in the same class of goods. Attentive readers of this journal cannot have failed to perceive that the advertising department is distinct from the editorial department. The publishers exercise all possible care to accept advertisements from responsible parties only, and our readers must be content with this. The editor cannot personally endorse advertisers, nor can he undertake to decide upon the relative standing of two rival houses. We hope that these few words will suffice to explain to our correspondents why it is that all their queries cannot be answered in the way they would wish.

THE PREVENTION OF PERINEAL LACERATIONS.

Since about thirty per cent. of child-bearing women have a lacerated perineum at some period in their lives, there is little wonder that this particular portion of the anatomy should receive a vast deal of attention. We regret to observe, however, that in these last years gynecological art has been much more devoted to the study of how to sew up the perineum than of how to prevent its laceration. It is not creditable to modern obstetrical art that so large a percentage of injuries occurs during parturition, that fifteen per cent. of women must be, and thirty per cent. are, torn. One might almost be tempted to think that if the perineum were not so much of a support to the obstetrician, he would support it in more effective style. This is perhaps an ungracious supposition, and it may be that, in fact, the modern perineum, like modern nerves and stomachs, is wearing out; and that perineasthenia is another mark of our pampered and overwrought civilization.

The directions given by obstetricians for preserving the perineum are sufficiently numerous, elaborate, and positive; but each one has his pet procedure, and the general practitioner is liable, after trying one or two, to drop into prophylactic nihilism.

This is not the case, however, with a physician of Lyons, France, Dr. Chassagny by name, who has devised an elaborate mechanical apparatus for the protection of the perineum (*L'Union Médicale*, 1888, p. 906). This consists essentially in a gutta-percha support, which is fastened to the thighs and applied so as to cover the perineum and inferior half of the vulva. By means of elastic lacings, a distention of the perineum in the transverse direction is permitted, but a downward stretching is impossible. The head is also thrown forward and made to glide under the pubis. How it works with the shoulders we are not told.

THE INTERNAL USE OF IODOL.

In an article in the *Berliner Klinische Wochenschrift*, 1889, No. 2, Dr. Dante Cervesato calls attention to the advantages of iodol in the treatment of those diseases in which iodine compounds are ordinarily used.

Dr. Cervesato employed the drug in a series of cases of scrofula, pulmonary troubles, and tertiary syphilis. He gave it in daily doses of from 0.50 to 1 and 1.50 gramme, never with any toxic effects. The results were uniformly good, and there were no digestive or renal disturbances. He, in some instances, applied an ointment of one part iodol to fifteen parts of vaseline upon enlarged glands.

In the treatment of phthisis, tubercular laryngitis, and chronic bronchitis the iodol was administered in the form of inhalations as well as by the mouth. For pur-

poses of inhalation the drug was suspended in a very fine emulsion.

No especial influence was observed upon the course of the phthisical processes in the lungs, but cases of tubercular laryngitis were decidedly improved.

In tertiary syphilis, also, all the effects usually obtained by the iodides were observed. The doses were one to three grammes daily.

Except in one or two cases Cervesato never observed any signs of iodism. Even acne occurred very rarely; the stomach functions were undisturbed, and appetite was even increased. No instance was noted of any effect upon the body temperature, circulation, or respiration. The urine was slightly increased in amount, as was also its percentage of urea. Iodine was present in the urine in small amounts.

The peculiarity of the drug is said to be that it is excreted from the body more slowly than are the iodides. Its tastelessness and general innocuousness make it preferable, as a rule, to the compounds of iodine at present in use.

In this connection we may refer to an article on "Hydriodic Acid," by Dr. William C. Wile (*Journal of the American Medical Association*). This writer speaks in high terms of hydriodic acid as a substitute of the iodides. He has used it successfully in chronic bronchitis, obesity, tertiary syphilis, chronic rheumatism, and in lead and mercurial poisoning.

News of the Week.

The Michigan Medical College held its Annual Commencement on February 28th. Degrees were conferred upon eleven graduates.

The Long Island Medical College Hospital held its graduating exercises on March 14th. Diplomas were bestowed on forty-seven students.

The Work of Swiss Surgeons in Plastic Surgery.—At a meeting of the Medicinische Gesellschaft, in Basle, Dr. Garré showed seven patients in whom skin-transplantation by Thiersch's method had been successfully performed. The method consists in covering the denuded area (after complete arrest of hemorrhage in surgical wounds, or after scraping off granulations in cases of ulcer, etc.) with the thinnest possible strips and slices of cuticle freshly removed from a living human body, preferably from the thigh or arm; and, having spread each graft evenly over the surface, the operator presses it down closely with a dry sponge, and then covers the whole area either with caoutchouc paper or protective salve, etc. The dressing is changed every two or three days. Almost invariably primary union follows, while the uppermost (dead) epithelial layer comes away in a few days. In one of Dr. Garré's patients, a woman, thirty-eight years of age, the whole of whose right arm was one granulating surface, the result of a burn, the entire area was skinned over in two sittings. Curiously enough, a few weeks after complete healing, intense itching was felt over the new integument; this, however, was speedily relieved by massage. Another patient, a boy fifteen years of age, in whom forcible extension of the contracted right elbow-joint had given rise to a deep rupture of the granulating surface down to the biceps, the denuded area measured 20 by 5 to 10 centimetres. Dr. Garré covered both the cutaneous surface and muscular wound with epidermoidal strips. The result was satisfactory in every way, the joint preserving perfect freedom of movement. In a third patient, a woman forty-one years of age, a third of the right leg was left denuded by a severe phlegmon. Some of the grafts measured from 10 to 14 centimetres in length, and from 4 to 6 in breadth. They were found to have united by first intention about the thirteenth day. In two other cases, where a plastic operation for union of the fingers was to be performed, Thiersch's grafting was resorted to in order to cover one of the two digital wounds, the other raw surface being covered with a cutaneous flap. In a sixth case, Dr. Garré transplanted several strips of cuticle to fill up the defect on the forehead left after a rhinoplastic operation. In the seventh case, a successful attempt was made by Dr. Huebscher to graft pieces of cuticle from a sucking pig two days old.—*British Medical Journal.*

Queen Victoria and the Forceps.—Dr. A. D. Macdonald, of Liverpool, writes to the *British Medical Journal*: "There is an historical fact which both 'Practitioners of the Old School' will do well to bear in mind, namely, that it is, in the providence of God, owing to the timidity of three doctors regarding the use of the forceps that Queen Victoria now occupies the British throne. If the forceps had been applied early in the labor of the Princess Charlotte, only child of George IV., and a living child and living mother had (as we have reason to expect) been the result, in all human probability the Princess Victoria would have remained the obscure daughter of Edward Duke of Kent. Our gracious Queen, and the British nation also, have, therefore, cause for blessing the author of the question-begging impotent fallacy, 'meddlesome midwifery is bad.' The phrase is almost fossilized already; in another generation it will be unheard of. I think the majority of modern practitioners agree in holding that 'dame Nature,' unaided, would nor infrequently play the part which she did in the Princess Charlotte's case."

The Berlin Laryngological Society is the name of a new society recently organized in Berlin. Dr. Bernhardt Fraenkel was elected president.

The Rabbit Commission of Australia report that the experiments with the virus of chicken cholera, for the purpose of exterminating the rabbits has been a complete failure. The microbes lose their virulence too readily.

A Bill for Establishing a State Board of Health for Nebraska has been favorably reported, and is likely to become a law. The sum of $5,000 is appropriated to carry out the provisions of the act.

Death by Electricity.—A bill has been introduced in the present session of the Alabama Legislature to put criminals to death by electricity instead of by hanging.

A Chair of Physical Examination for Life Insurance has been created in the University of Vermont, and Dr. Charles F. Stillman, of New York, has been elected as its first incumbent.

Dr. Henry F. Sears has offered to present the Harvard Medical School with a building for a pathological and bacteriological laboratory, not to cost over $30,000, and the donor to name the architect.

DEFEAT OF MEDICAL BILLS.—The Connecticut Legislative Committee has reported adversely upon the bill regulating medical practice. A similar bill in the Rhode Island Legislature was lately defeated by a small vote in a thin house, as was also a bill for the same purpose in Tennessee.

THE LANGENBECK MEMORIAL.—The German physicians of this country have so far contributed $2,053 to the Langenbeck Memorial.

ANTIFEBRIN has been used successfully in a case of tetanus by Dr. Flammarion.—*Bulletin Général de Thérapeutique.*

DR. GOWERS has resigned his position of Assistant Professor of Clinical Medicine at the University College, London.

PENNSYLVANIA IS THE ONLY STATE, so far as we know, which gives financial help to its private medical colleges. "From time to time," says the *American Lancet*, "the medical colleges of that State have secured money in smaller or larger amounts from the Legislature. Last year the Medico-chirurgical College succeeded in obtaining an appropriation. This year the Philadelphia Polyclinic seeks at the hands of the public purse the means for the erection of a building better suited to its needs. Some years ago Jefferson Medical College secured a couple of hundred thousand dollars for the erection of a hospital. How much the University of Pennsylvania and other medical schools have obtained from the same source we do not at this moment recall, but the amounts are very considerable."

NASAL SURGERY IN PARIS.—It seems that in France surgeons are more and more renouncing the great operations and resections which were once much in vogue there for the cure of naso-pharyngeal polypus. This operation used to cause very considerable mortality from secondary hemorrhages and cerebral complications, of which M. Verneuil has reported many examples. The course now pursued is rather that which M. Trélat has brought into repute at the Paris hospitals, namely, limited resection of the palatine arch, as described by Nélaton, followed by destruction of the polypus by electrolysis, or by the actual cautery, or chloride of zinc, the various prolongations of the polypus being thus attacked and the risk of relapse considerably diminished.—MR. ERNEST HART, *British Medical Journal.*

THE CRAZE FOR SPAYING WOMEN is fast dying out in New York. It is now conceded by the most aggressive gynecologists here that the operation has been fearfully abused. There can be no doubt that the operation is sometimes necessary, but the wholesale sacrifice of ovaries that was once so prevalent here, and from whence some of our Western gynecologists caught the infection, is a thing of the past. I have seen two cases here, but in each the ovaries were extensively diseased and the tubes distended with pus. They were a constant source of pain and sickness to the patients, who were incurably sterile, and the proper thing to do was to take them out. But they presented a striking contrast to the normal tubes and ovaries that I have seen exhibited, in times past, to the Marion Country Medical Society.—New York Correspondence of the *Indiana Medical Journal.*

THE KNIFE *vs.* ELECTRICITY.—Electricity and the knife are about waging war with each other. Dr. Robert Newman has consented to test the methods of electrolysis as against the urethrotome in strictures. We are told that Dr. E. S. McKee, of Cincinnati, who believes in the efficacy of Apostoli's methods of electrical treatment in gynecology, has accepted the challenge of a Pittsburg physician, Dr. Sutton, who believes in the knife.

THE MEDICAL PROFESSION OF A WESTERN CITY.—There are 92 persons practising medicine in Memphis—1 to 633 of the city's inhabitants. Eighty-one of these claim to be "regulars"—4 are homœopathic, 2 eclectic, 2 "practitioners," 1 thompsopathic, and 2 fail in attempting classifying themselves. Of these 1 graduated in the year 1839, 1 in 1841, 1 in 1848, 7 in the 1850 decade, 19 in that of 1860, 20 in that of 1870, and 25 between 1880 and 1889. Eleven never graduated.

INTERNAL URETHROTOMY, performed with Maisonneuve's instruments, is still the mode of treatment most used in strictures of the urethra which are rebellious to dilatation, but only under those circumstances. M. Guyon related to the Société de Chirurgie in 1886 the results of his practice in this respect. He had had 457 urethrotomies in twenty years, with 20 cases of death, of which 17 only were attributable to the operation. In these 17 cases the patients were all suffering from grave and old renal lesions. It is, however, considered that the harmlessness of the operation has greatly increased since the employment of antiseptic precautions. The sound is left in for twenty-four or thirty-six hours after the operation. —MR. ERNEST HART.

HYSTERIONICA BAYLAHNEN, a resinous plant indigenous to Chili, has been found to be an efficient drug in the treatment of diarrhœa and dysentery.—DR. G. BAILLE, *Bulletin Général de Thérapeutique.*

TETANUS IS AN INFECTIOUS DISEASE OF EQUINE ORIGIN.—Such is the doctrine of M. Vérneuil, advocated recently before the Académie de Médecine.

A THIRD CASE OF CURE OF AORTIC ANEURISM BY LIGATING THE RIGHT COMMON CAROTID AND SUBCLAVIAN ARTERIES.—At a meeting of the Southern Surgical and Gynecological Association Dr. F. T. Meriwether, of Asheville, N. C., reported a case of aneurism of the ascending aorta, involving the innominate artery, which was operated upon by him at the Mission Hospital at Asheville, N. C., on November 3d. The patient was thirty-seven years of age, female, no history of syphilis. The aneurism was primarily only in the ascending portion of the arch, but while under observation it began to involve the innominate. The right common carotid and subclavian arteries were tied with strong catgut. On the eighth day the dressing was removed and union had taken place. Not a drop of pus or exudate had discolored the gauze. No bad symptoms followed the ligation, and the bruit and pulsation decreased every day. She was discharged as cured on the twenty-first day. As well as could be determined the aneurism was three inches in diameter. This is the third case ofo peration upon aneurism of the ascending aorta, and the second cure, Wyeth, of New York, reporting one in 1880 as a cure, the patient dying one year afterward.—*North Carolina Medical Journal.*

PYROTOGENINE is the name of a toxic substance, the product of microbic life, which, according to MM. Roussy and Hayem, causes fever. Other less powerful substances, also isolated from microbic cultures, are called catorigenous poisons. Still other substances, which lower temperature, are called *frigorigènes*.

THE INTERNATIONAL CONGRESS OF DERMATOLOGY AND SYPHILOGRAPHY will be held in Paris, at the Hôpital St. Louis, August 5 to 10, 1889. Those intending to present communications should send word to Dr. H. Feulard, Hôpital St. Louis, Secretary of the Committee of Organization. The subjects of lichen, pityriasis, rubra, pemphigus, and the treatment of syphilis are among those to be discussed.

LIME-WATER IN DIABETES.—Dr. Theo. Clemens claims that the use of ʒ j. to ʒ ij. of lime-water daily will prevent the tendency to diabetic coma in the diabetic.—*Allgemeine Central-Zeitung*, No. 14, 1889.

THE ELECTRIC LIGHT (arc-light) contains chemical rays which, according to Maklakow irritates the conjunctiva and even the skin. Dr. Maklakow has produced an actual erythema of the skin simply from exposure to the light.

UTERINE "TONICS."—A correspondent writes to us with some indignation regarding the invasion of his office by agents bearing specimens of uterine "tonics." The composition of these preparations is usually as vague and vegetable as that of many widely advertised compounds, while the claims put forth for them are quite as extravagant. What a uterine "tonic" is, however, our correspondent does not know and would like to learn. Is it, he asks, antiphlogistic or antimicrobic, constrictive and ecbolic, or vaso-motor and hyperplastic? We quite agree that so vague a term as "uterine tonic" should be expunged from medical nomenclature.

THE FREQUENCY OF DISEASE OF THE UPPER AIR-PASSAGES.—Of 2,000 children examined by Dr. Franklin Chappell, of this city, 1,231 were found to be suffering from some anatomical abnormality of the upper air-passages; and in the majority of the cases there were symptoms of respiratory obstruction and catarrh.

THE NUMBER OF DRUGS in the German Pharmacopœia is only 606; in the Austrian, 560; in the Norwegian, 530. The United States Pharmacopœia contains 1,010; the English, 815; the Belgian and Spanish, about 1,500; while France leads the world with 2,000 drugs.

TUBAL DISEASE.—Professor Gusserow, of Berlin, reports thirty-one cases of removal of the Fallopian tubes for pyosalpinx. All the thirty patients recovered, with the sole exception of one, in whom a small piece of the diseased tube was left behind and fatal septic peritonitis ensued. Gonococci were sought for under the microscope, in some cases, but could not be found. The pus from diseased tubes produced no results when introduced into the peritoneal cavities of rabbits. Dr. Gusserow holds that the symptoms of pyosalpinx are those of chronic perimetritis, and that no special diagnostic feature can be distinguished. He takes the not very novel view that pyosalpinx is a serious malady, incapacitating women of the working classes, and exposing them to danger from rupture of the distended tube.

SUICIDE OF PROFESSOR SOYKA.—Professor Soyka, of Prague, shot himself through the head with a revolver in his house in Prague on the 23d ult. Professors Gussenbauer, Kahler, and Pick, who were called immediately, found Dr. Soyka still alive, but he died soon afterward. He had suffered from extreme nervous irritability since the death of his brother, a distinguished lawyer, who died in a lunatic asylum in Vienna last year. On the table of the room in which Professor Soyka committed the fatal act, a slip of paper was found on which he had written the following words: "Dear Brother, I follow you. Where thinking ceases, shooting begins. It is better to die than to go mad."

PICROTOXIN is a very effecient antidote to morphine poisoning, according to Professor Bokai. It stimulates the respiratory centre and can be given more freely than can atropine.

AN ELABORATE DISSECTION.—A notable preparation was recently finished by Dr. R. B. Weaver, of Philadelphia. It is a dissection of the entire cerebro-spinal nervous system displayed in one piece, all the nerves, both cranial and spinal, being traced to their termitral filaments. The brain alone, for obvious reasons, is not preserved, as this is a dry specimen. The dura mater, however, is retained entire, and, being filled with curled hair, its form is preserved and it constitutes a *point d'appui* for a display of the cranial nerves as nearly as possible in their relative positions, which is accomplished by means of fine wires bent in conformity to the course and direction of the several branches, and to which the nerves are attached. The eyes are also preserved, with the optic nerves, the coats being distended with a hard injection. The membranes of the cord are laid open, exposing the roots of the spinal nerves. The nerves are stripped of all extraneous tissue down to the sheath, and the whole dissection is so admirably mounted as to display almost at a glance the whole system in detail. Nearly five months of unremitting labor, from eight to ten hours a day, were expended in the dissecting and mounting of this specimen.—*New York Medical Times.*

A SCHOOL FOR CHILDREN WITH RINGWORM.—Mr. Ernest Hart writes from Paris to the *British Medical Journal* of a recent addition to the Hôpital St. Louis, viz., a school for children suffering from ringworm. The opportunities at disposal for treating such children in the wards and the hospital being insufficient—and, on the other hand, children suffering from ringworm being excluded from schools—the administration of the Assistance Publique of Paris has opened, in some buildings attached to the hospital, a school in which these children are at the same time medically cared for and taught. They come every morning and return home in the evening. This valuable service has been working for two years, and it has proved so useful that the question is now being entertained of establishing another similar school in another part of Paris; Dr. Quinquaud is in charge of it.

INSOLATION IN A YOUNG CHILD.—Dr. A. L. Hodgdon reports in the *Maryland Medical Journal* of December 15, 1888, a case of sunstroke occurring in a child four years of age. It was successfully treated by the cold bath and tincture of aconite.

Society Reports.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 23, 1889.

WILLIAM P. NORTHRUP, M.D., PRESIDENT, IN THE CHAIR.

DR. H. J. BOLDT presented some specimens of

CYSTIC OVARIES

illustrating the difficulty sometimes encountered in the diagnosis of ovarian tumors. The patient was thirty-nine years of age, and had been married twenty-one years. She had had two children, the last one having been born eighteen years ago, and one miscarriage five years ago. During the past six months she had been ailing, complaining of a pain in the right inguinal region, and losing flesh. She was cachectic-looking, her muscles were soft and flabby, and the abdomen was somewhat distended by ascites. On the left side there could be felt a tumor which seemed to be about the size of an infant's head, lying to the left of the median line and a little above the umbilicus. The tumor was smooth and movable. On the right side, in the hypogastrium, a number of nodular masses were to be felt which were continuous with other nodules extending into the right inguinal region. The uterus was displaced upward by a mass in the cul-de-sac. The tumor on the left side was taken to be a solid tumor of the ovary, and that on the right side to be a malignant growth. The patient was constipated, and when the bowels did move nothing was passed but scybalæ.

On making an incision through the abdominal wall a mass appeared at the opening which presented all the appearances of a papilloma. The incision was carried up in order to ascertain what was the nature of the tumor on the right side, and it was then found to be an ovarian cyst. The tumor on the left side was also seen to be of the same nature.

The history of this case showed, Dr. Boldt said, that one cannot be too careful in making a diagnosis in cases of abdominal tumor, for had he adhered to his first opinion that the case was one of cancer the patient would have been allowed to go unrelieved. The papillomatous growth which had appeared at the wound was found to be attached to the cyst of the right ovary. This was referred to the Committee on Microscopy for examination.

DR. ELIZABETH M. CUSHIER presented some specimens showing

FIBRO-SARCOMATA OF THE UTERUS AND LIVER,

removed post mortem from a woman, fifty-two years of age. The patient, a native of Ireland, had been married twenty-six years, and had had eleven children and two miscarriages, these last occurring in the same year, twelve years ago. Since that time she had not been pregnant. Her family history was negative. Menstruation had always been regular, profuse, from five to seven days in duration, painless, and recurring every three weeks. One year ago the patient had a severe uterine hemorrhage, after which the flow became excessive, and three months later ceased. The month following this the patient began to be troubled with nausea and vomiting, and since that time had been able to take only liquid food. Six months ago she first noticed a swelling of the abdomen, beginning in the epigastric region and extending downward and to the left. She had had very severe pain in the epigastric and hypochondriac regions, dating from about the same time. She was admitted to the Infirmary of the Woman's Medical College on December 26, 1888. She was at that time greatly emaciated, jaundiced, with dry and coated tongue, and greatly distended abdomen. On palpation in the epigastric region a large, hard mass could be felt extending downward half way to the umbilicus, and continuous with a mass in the left hypochondrium, which reached four inches below the ribs. There was dulness over this entire region, and dulness also in both flanks. The uterus could be felt as a firm uniform tumor reaching half-way to the umbilicus. The circumference of the abdomen at the umbilicus was 38¼ inches. Urine high colored and scanty, and contained ⅛ albumen.

The condition of the patient did not materially change while she was under observation, excepting that there was a perceptible increase of the abdominal tumor. She took but little nourishment, and complained constantly of pain when not under the influence of morphine. The sensorium was unaffected, and the patient greatly desired an operation, hoping to gain relief, but it was decided that nothing could be done.

The woman's strength gradually failed, and she died on January 18, 1889. At the autopsy, made eight hours after death, many recent adhesions were found between the visceral and parietal peritoneum. The liver was enormously enlarged, and studded with soft, irregular, yellowish nodules, an aggregation of the latter at the lower portion of the left lobe forming a mass the size of a small fœtal head. The liver was adherent to the diaphragm, and to all surrounding viscera. The stomach, which was firmly adherent to the liver, had been so displaced that it occupied a vertical position to the left of the median line. The transverse colon and small intestines were adherent to each other, and to the lower and posterior surfaces of the liver. The spleen was adherent, otherwise normal. The kidneys were slightly enlarged and soft, capsule free, and presented no nodules. The heart was normal. The lungs were compressed by encroachment of the tumor, and congested posteriorly, otherwise normal. The uterus was the size of the gravid organ at four and a-half months. Its walls were uniformly enlarged excepting at one point on the right side where there were three soft nodules about the size of a hickory nut. The glands were nowhere involved. Upon section of the liver it was found studded with nodules, varying in size from a pin's-head to a hickory nut. The central portion of the left lobe was almost wholly converted into a soft nodular mass. Elsewhere the nodules were distinctly circumscribed, and limited by liver tissue, which was apparently unaffected by the neoplasm. The liver weighed sixteen pounds. The uterus, upon section, presented the firm, white fibrous structure characteristic of uterine fibromata. The nodules were, however, much softer than the surroundig structure. The mucosa was intact.

Microscopic examination of the nodules of both the liver and uterus gave the characteristic spindle-cells, with large, clear nuclei, of fibro-sarcoma. So completely were the tissue-elements of both organs replaced by the cells of the neoplasms, that it would have been impossible to distinguish liver from uterine tissue in the sections under the microscope.

The points of interest were—first, the comparative rarity of sarcoma of the liver; second, the still greater rarity of the growth as a result of metastases from sarcoma of the uterus. In the literature on the subject, Dr. Cushier had not found any case in which the disease in the liver was secondary to a primary sarcoma of the uterus. That such cases do exist, and are reported, is more than probable, she said, but the difficulty in finding them points at least to their infrequency.

A question naturally arises as to whether certain cases which have been reported as primary sarcoma of the liver may not have had their origin in an obscure sarcomatous nodule of the uterus, that favorite site of fibroid neoplasms which are so closely allied to sarcoma.

DR. BOLDT said that these metastases in the liver from sarcomata of the uterus were certainly very rare. He had never seen such a case.

DR. H. A. C. ANDERSON presented a specimen, showing

CONGENITAL OCCLUSION OF THE DUODENUM,

removed from the body of an infant. The child was born at eight and a half months, and was, to all appearances, perfectly healthy. It was soon noticed, however, that it

could not swallow, and on the third day after birth it began to vomit a greenish-black fluid. The vomiting continued until the evening of the fourth day, when the child died. At the autopsy all the organs were found to be normal and well formed, except the duodenum. About one inch of this portion of the intestine, in close proximity to the pylorus, was absent, each end above and below the deficiency forming a perfect cul-de-sac. About one drachm of meconium was found in different parts of the small intestine, while about one ounce of it was in the stomach. The speaker was at a loss to explain the presence of the greater portion of the meconium in the stomach.

Dr. Holt asked whether the child's bowels had moved after birth.

The President inquired in what portion of the intestine the bile-duct opened.

Dr. Anderson said that the child's bowels had not moved. In the moment of surprise caused by the peculiar condition found, the position of the opening of the bile-duct had not been noted. He said that the occlusion was perfect, for the intestines had been injected, first with water and then with air, but there was no escape of either at the point of deficiency.

Dr. Freeman said he had made some search into the literature of this subject, but had found no case similar to this. In looking for an explanation of the presence of the greater part of the meconium in the stomach, we must first consider what meconium consists of. It is made up of what is swallowed by the fœtus, of the intestinal, and of the biliary secretions. There might have been a double bile-duct discharging both into the stomach and into the intestine. Or the bowels might have moved, and then the meconium have been swallowed.

Dr. Anderson said that there had been no motion of the bowels before birth, for the amniotic fluid was perfectly clear.

The President thought it most probable, as had been suggested by Dr. Freeman, that there were two bile-ducts, the larger one emptying into the cul-de-sac of the pylorus.

Dr. B. Farquhar Curtis gave a demonstration of Nothnagel's experiments in the

PRODUCTION OF INTUSSUSCEPTION

by an electrical stimulus applied directly to the intestinal walls.

The Society then went into executive session.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 21, 1889.

Alfred L. Loomis, M.D., President, in the Chair.

Dr. Charles McBurney read a paper (see page 312), entitled

THE RADICAL CURE OF INGUINAL HERNIA.

Dr. L. A. Stimson opened the discussion. He had come expecting to express his conviction of the value of the method which Dr. McBurney had described so clearly that anyone would be able to practise it. The necessity for restoring the peritoneal surface to its condition seen in those not cursed with hernia, was appreciated by all. His remarks, therefore, would relate chiefly to the latter steps of the operation; and he took occasion to say that Dr. McBurney deserved much credit for so ably attacking the idea that cicatricial tissue could not be depended upon for resisting strain placed upon it; for that was the argument commonly advanced against methods which sought the cure of hernia, the essential steps in which consisted of the formation of cicatricial tissue.

The advantages which Dr. McBurney's method offered were, first, the great freedom which it offered from the risk of septic process, of infiltration of pus, and spreading of phlegmonous processes originating in the wound situated at the peritoneal cavity. The upper part of the wound, from which septic processes might originate and prove very dangerous, was entirely open, and there could be no possibility of imprisonment of the inflammatory products. When the method was first introduced he was not favorably impressed by it, as it seemed to confine the patient unnecessarily long before recovery, and he thought of doing an operation which would give an equally efficient plug from granulation, and yet permit of recovery in about two weeks. He practised that method until he had, he said, endangered the welfare of quite a number of patients, and then gave it up entirely because, contrary to his expectations, recovery was often prolonged as much as in Dr. McBurney's operation, while the security against a return of the hernia was not quite as great. His method consisted in introducing a drainage-tube into the canal well up near the stump, and leaving it there, perhaps a week or two weeks, until granulations developed about it and, finally, after the drain had been removed, filled the canal with a cicatricial plug. As stated, he had abandoned the method for that of Dr. McBurney.

The reason, he supposed, why all did not have hernia was that the inguinal canal had at its internal opening a valvular arrangement which, when perfect, absolutely protected the canal from any distending force. In an old hernia there was no longer a canal, the internal ring having been dragged down until it reached and overlapped the external ring, and thus, instead of a canal with a valvular arrangement, there was only a hole in the abdominal wall, closed by peritoneum on one side and skin and subcutaneous fascia on the other. It was necessary in alternative measures that the ring should not simply be narrowed; there should be restoration of the canal, which, however, had not yet been accomplished. He knew of no way in which the valvular structure of the inguinal canal could be restored. At the time of operating it often looked as if it had been restored, but the subsequent history of the cases proved this view to be false. It not being possible to restore the inguinal canal to its normal condition, an alternative measure must be found which would furnish adequate support. Such a measure was Dr. McBurney's. The plug which that operation furnished was not less than the periphery of the ring; it extended even beyond it, overlapping it on both sides and binding it together in one solid mass. The plug could not be pushed forward because of its strong fibrous envelope. The only fear with regard to the efficiency of the method which he had entertained was the possibility of a hernia occurring at the margin of the cicatrix.

Dr. A. G. Gerster expressed appreciation at the lucidity of Dr. McBurney's paper. To lucidity it added another virtue, that of brevity. The question of cure of inguinal hernia was rather in the experimental stage; there was but one reliable test of any procedure, and that was time. The operative procedure could be divided into two steps; the first being the exposure and treatment of the sac. All now agreed that it was best to reach high upon the sac and deligate, in order to avoid the funnel-shaped depression in the peritoneal surface which led to hernia. The slitting up of the anterior wall of the inguinal canal, as done by Dr. McBurney, facilitated this step most remarkably. But all operations for cure of hernia were more or less complicated and difficult, because of the varying conditions in different individuals.

Referring to Dr. McBurney's remarks on the strength of the cicatricial plug, he said there was another class of laparotomy cases not mentioned, in which the conditions were more like those existing after his operation for inguinal hernia, and in which there was a strong tendency for the development of ventral hernia. He referred to the laparotomy cases in which an intra-mural abscess formed, resulting after healing in a cicatricial plug with conditions back of it similar to those which Dr. McBurney tried to obtain in his operation; yet in those very cases hernia often developed subsequently. The cicatrix got thinner and thinner, and finally ventral hernia took place.

Thus the decision as to the curative value of Dr. McBurney's operation must be determined by time.

Dr. Robert Abbe said that a year ago, when this operation was discussed at the Surgical Society, he thought it would be likely to prove defective, in leaving a cicatrix which resembled the median cicatrix left by laparotomy in which ventral hernia formed; but subsequently he tried it, and now, after its performance in seventeen cases, he had become convinced that it was the best yet employed. He had operated by different methods about one hundred and seventeen times, in the first fifty-two of which he did Macewen's operation. Macewen, when asked by other operators why they did not succeed in securing a radical cure, said it was because they did not do the operation properly. Dr. Abbe was of opinion that an operation which could be done properly or successfully only by the one introducing it, was not a correct one to offer the profession. He was sure that remark did not apply to Dr. McBurney's. One of the chief objections to Macewen's operation was the fact that the hernial sac was extremely variable, being sometimes as thin as tissue-paper, and it was impossible then to obtain a boss inside to prevent subsequent recurrence. He knew this to be true in one case, in which he did Macewen's operation on a hernia on one side, and McBurney's on a hernia on the other side. The patient died of another affection two weeks afterward, and he found at the autopsy that Macewen's operation had not produced the boss claimed for it. On the other side there was a smooth peritoneal surface, as Dr. McBurney had stated existed after his procedure. There was great liability to submural abscess after Macewen's operation. That which especially recommended Dr. McBurney's was its extreme simplicity, so that any practitioner could perform it. He had not felt that it was safe to leave the patient without any support for some time subsequently, and consequently advised the use of a light truss.

Dr. McCosh had the records of four cases in which Dr. McBurney's operation had been performed, fifteen months ago, and in none had there been a return. Other cases of more recent date showed no return. It had often occurred to him that it might be dangerous to leave such a hole in the abdominal cavity during granulation, lest intestines should escape, and this had taken place in one of his patients, who in a fit of delirium got out of bed, attempted violence, and tore open the wound. This danger could be overcome by suitably placed sutures.

Dr. Hartley had tried Macewen's, Ball's, and other methods, but found none equal to that described by Dr. McBurney. The latter best overcame the tendency to a funnel-shaped opening inside, which was the great productive cause of hernia. He had never seen the necessity for using a truss after Dr. McBurney's method.

Dr. F. W. Murray thoroughly endorsed Dr. McBurney's operation. He presented a man operated upon last fall for double scrotal hernia of twenty years' duration. Since 1882 the man had been quite helpless, the herniæ were irreducible. There had not yet been any return.

Dr. Syms also endorsed the author's method of operating, and mentioned a case in which he had performed it, six months ago, there having been no return. The sac had contained fourteen feet of intestine.

Dr. V. P. Gibney had had no experience with McBurney's operation, but he had seen fewer returns after its performance, in patients who came to the hospital, than from any other method. There had been some, but he afterward learned that the method had not been fully observed by the operator. It had been argued that, if a hernia was operated upon, it could subsequently be better controlled by a truss, but the last year or two he had seen patients with quite an extensive cicatrix, whose hernia it was very difficult to retain with a truss. With regard to the behavior of cicatricial tissue, he had found in the operation for shortening the tendo Achillis that there was a strong tendency for the V-shaped cicatrix left after the operation to become elongated. The cicatrix, however, was stronger when formed after granulation of an open wound. Of course, there was not the same strain brought to bear upon the plug after McBurney's operation for hernia.

Dr. McBurney closed the discussion, and said with regard to the test of time, that Macewen's patients showed no greater tendency to return between the first and fourth years than after the fourth year. He had himself refused no case excepting that of a man whose hernia was but a trifle compared with his other ailments. He did not mean to say, however, that he would operate in all cases. As to approximation of the two rings, it should be borne in mind that, while the inner edge of the internal ring was brought down toward the external ring, the upper edge remained in the one place. On splitting up the canal it would be found that the sac could be lifted an inch or an inch and a half farther.

Dr. Laurence Johnson was elected trustee for unexpired term.

Dr. A. Jacobi had read an article from *The Evening Post*, stating that the Legislature had passed a bill, permitting a county to withdraw its insane from State institutions, to be cared for in its own institutions. This was done in the face of the fact that there was a bill providing for State care of all indigent insane which had not yet been reported upon by the committee. Dr. Jacobi then read a lengthy resolution, which was adopted by the Academy, disapproving of this act of special legislation, and urging the passage of the bill approved of by the State Charities Aid Association, providing for State care of all indigent insane.

Stated Meeting, March 7, 1889.

Alfred L. Loomis, M.D., President, in the Chair.

THE TREATMENT OF ACUTE AND SUBACUTE NEPHRITIS.

Dr. Francis Delafield said that in bringing this paper before the Academy he must acknowledge at the outset that he had no new drug to propose, no new plan of treatment to advocate. It was rather, if possible, to determine how plans of treatment and drugs already employed were to be intelligently applied in individual cases of acute and subacute nephritis. To give an idea of the methods of treatment ordinarily employed he quoted shortly from French, German, and American authors. It was evident from the quotations that the writers' main object was to make up for diminished quantity of urine by acting on the skin and intestines, and that they regarded as the principal danger of acute nephritis accumulation of excrementitious substance in the blood. Some of the authors, in addition, believed they could rest the kidneys, while inflamed, by producing diaphoresis or catharsis, and that such rest would diminish the severity of the nephritis. Some thought that by sufficiently large ingestion of fluids the inflammatory products could be washed out of the kidneys. Digitalis was regarded with apprehension by some, while others warmly advocated its use. Morphine in considerable doses was employed by some for the relief of uræmic attacks, and in small doses by others to relieve vomiting and restlessness, while still others deprecated its use under any circumstances. General blood-letting seemed to be restricted by most to nephritis of pregnancy, attended from the first by high temperature, and cerebral symptoms. The disposition at the present time to direct attention and treatment to the symptoms of nephritis, rather than to the nephritis itself, was so general that he thought it might be wholesome to look at the subject from the opposite point of view, and to direct attention, not to the function of the kidneys but to the kidneys themselves.

In order to do this it was necessary at once to separate cases of acute nephritis from those of subacute nephritis, for in the two states the condition of the patient was altogether different.

First, of acute nephritis, most cases met with compli-

cated scarlatina, diphtheria, or pregnancy, less frequently one of the infectious diseases or severe inflammation, or as a primary lesion. In all cases there was congestion and exudation. The exudate consisted of three elements, in varying proportion—serum, white blood-cells, and red blood-cells. There might be swelling of the tufts of the glomeruli; degeneration and death of the renal epithelium; growth of new connective tissue in the stroma of the kidney. According to the severity of the nephritis would there be symptoms of varying number and severity. There were in the urine albumen, casts, red and white blood-cells. In more severe cases there were constantly additional symptoms of fever, prostration, loss of appetite, nausea, vomiting, anæmia, and, in some of the more severe cases, also headache, delirium, stupor, convulsions, labored heart-action, hypertrophy of the left ventricle, pulse of high tension, and dropsy. In the cases in which the urine was suppressed a number of days, the patient had alternating stupor and delirium, and passed into a typhoid state. The regular duration of a fair-developed acute nephritis seemed to be about four weeks. The natural termination, whether with or without treatment, was in recovery, but the more severe cases might prove fatal. The cases in which there was, from the first, a growth of new connective tissue in the stroma were likely to become chronic.

What were the indications for treatment? Evidently, in the very mild cases, no treatment was necessay, except to keep the patients in bed, and on a fluid diet. In the more severe cases it was often proper to interfere, in order to secure greater comfort and safety for the patient. The first condition which called for treatment was the nephritis itself. In treating this, it was to be remembered that although the quantity of urine voided was small its quality was good, for it contained a fair proportion of excrementitious solids to the ounce of urine; that the secretion of urine must necessarily relieve the congestion of the kidneys, so that it was better that the kidneys should perform their function than be at so-called rest; that, so long as the congestion of the kidneys persisted, the quantity of the urine would be diminished; that a considerable diminution in the quantity of urine, continued one or two weeks, was often perfectly well borne by the patient. It was not, therefore, necessary to pay attention to the diminished quantity of urine, and try and make the skin or intestines do the work of the kidneys. It was wiser, by relieving congestion of these organs, to enable them to do their work, knowing that the moment they began to do this their congestion would be still further diminished, and that, though the nephritis continued, the excretion of urine might then be sufficient. Fortunately we had at command means by which the congestion of the kidneys could be diminished—not completely, it was true—but partly, for short periods. These means were to cause the blood to collect at the surface of the body by the application of heat to the entire skin, the use of dry or wet cups or heat over the lumbar region, the empirical use of calomel or sulphate of magnesia, in small doses, repeated at short intervals until the bowels began to move; the use of such drugs as would decrease the increased arterial tension. While the nephritis was still active, it was not expected by any means that the urine would be brought up to its full normal quantity, but only that a sufficient quantity should be passed to insure the safety of the patient. The febrile movement required no treatment. The prostration, nausea, and vomiting only called for rest in bed, and fluid diet. The anæmia ought unquestionably to be prevented or relieved, but while the nephritis was active he knew of no way in which this could certainly be done. When convalescence was established, the anæmia improved under ordinary methods.

The cerebral symptoms were those to which most attention had been directed. There could be no question that they regularly accompanied contraction of the arteries with increased tension and labored heart-action. No matter what views one entertained as to the cause of this change in the circulation, he believed the treatment was best directed to the arteries themselves rather than to an uncertain cause of the contraction. Fortunately there were drugs which acted promptly and efficiently for this purpose, and of these the most suitable were aconite, chloral hydrate, and opium, preferably given in small doses at regular intervals, so that their use could be continued for some time. It was wise to watch the condition of the heart and arteries, and as soon as increased arterial tension developed not to wait for the manifestation of cerebral symptoms, but relieve it at once. The treatment of a case of acute nephritis, therefore, resolved itself into the treatment of the nephritis itself, and of the contraction of the arteries which might accompany it. To carry out this treatment he could, from personal experience, strongly recommend the following routine: The patient was put to bed, the entire skin washed every day, and for two successive days drachm-doses of the sulphate of magnesia were given every hour until one ounce had been taken or until the bowels began to move; after this the tincture of aconite was given in doses of a minim every hour. Within a few days the albumen in the urine would be found diminished, the pulse soft, the dropsy would have disappeared, but the patient would still be anæmic. The milk was then to be gradually replaced by solid food, and iron and oxygen given.

As to subacute nephritis, the distinction between acute, subacute, and chronic inflammation was an arbitrary one, but was often of real convenience. This was especially true of nephritis. As opposed to the conditions described in acute nephritis, in the subacute form the inflammation was long-continued, there was no congestion, the exudation was of the profuse, almost dropsical, character met with in other subacute inflammations, as pleurisy with effusion; there were permanent changes of the stroma and glomeruli of the kidney. The interference with the function of the kidney did not relate to the quantity of the urine, for that was often in excess, but with its quality, the proportion of solid matters decreasing as the disease advanced. The symptoms were largely due to the effect of the nephritis on the composition of the blood and the nutrition of the body. The anæmia, dropsy, and loss of strength were prominent features of the disease. Contraction of the arteries was absent, or present only at intervals. The cerebral symptoms were chronic rather than acute. It might happen, however, that in the course of the subacute nephritis there would be exacerbations of the inflammation during which the changes in the kidneys and the symptoms were the same as those of acute nephritis. Subacute nephritis was especially common as a primary disease, and as a sequel of scarlatina and diphtheria. The patients lost strength, became anæmic, suffered from nausea, vomiting, diarrhœa. There might be inflammation of the retina, the arteries were for the most part relaxed, but might sometimes be contracted; dropsy was apt to be a marked symptom. The urine might be somewhat diminished, but was often in excess; the specific gravity and quantity of solid matters diminished as the disease progressed. The quantity of albumen was considerable. Some patients continued to get worse in every way, and died within one or two years; some exhibited a part or all of the symptoms for weeks or months, and then seemed to be better, or might again become ill, and thus go on for years, sometimes better, sometimes worse. A very few patients seemed to recover permanently.

The conditions which required treatment were: 1, The subacute nephritis; 2, the changes in nutrition and in the composition of the blood; 3, the dropsy; 4, the condition of the arteries; 5, the cerebral symptoms; 6, the acute exacerbations of the inflammation.

For the nephritis, the best treatment was residence in a suitable climate, which should be warm, and where the patient could lead an out-of-door life. If the patient resided in a cold climate, it would be necessary to confine him to the house much of the time. Except during the

exacerbation the patient should take as much of solid foods and of fats as he could digest. The excessive use of milk and of mineral waters was to be avoided. It was possible that the use of opium or of the bichloride of mercury might favorably affect the nephritis. The anæmia was the most important symptom, and it was most efficiently treated by the internal use of iron, the inhalation of oxygen, combined with massage and relief of constipation. With this treatment in many patients the improvement was satisfactory, but in some no such improvement took place.

The dropsy might never be more than an inconvenience, or it might be the most distressing feature of the case. It was apt to reach its greatest development with low arterial tension and often with large excretion of urine. In some cases the treatment of the anæmia and the regulation of the diet would answer at the same time for the treatment of the dropsy. In other cases different means must be employed. When subacute nephritis had lasted any length of time, the quantity of urea excreted fell to six grains, or even less, to the ounce of urine, and the patients should therefore pass daily seventy or more ounces of urine. It was wise not to increase the urine more than would be sufficient to enable the patient to excrete his five hundred grains of urea a day. The quantity of fluid which he took should be proportioned, as far as possible, to the quantity of urine passed, not allowing the former to exceed the latter when removal of dropsy was desired. In extreme cases of dropsy it was necessary to purge, sweat, puncture the skin, tap the serous cavities; but when these measures became necessary, it meant that the case was an unfavorable one.

The condition of the arteries and of the left ventricle of the heart should be watched throughout the disease. High arterial tension might be controlled by nitro-glycerine, chloral hydrate, or opium. Low arterial tension should be heightened by digitalis, or ergot; but thus heightening the arterial tension he had not found to be serviceable to the patient. To avoid cerebral symptoms, one had constantly to watch the excretion of urea and the condition of the arteries. The quantity of urine should be kept large enough to make up for its diminished solid constituents. Increased arterial tension should be at once relieved. The acute exacerbations of subacute nephritis could be managed in the same way as an attack of acute nephritis.

Dr. Thomas E. Satterthwaite sent his views on the treatment of acute and subacute nephritis in writing, but they were not limited strictly to those forms of inflammation, and therefore were not entirely applicable to the discussion. There were two facts, he said, which should be borne in mind: 1, That there were quite different pathological conditions underlying the several manifestations of these affections; 2, that very few cases were primary. He did not wish to appear as pretending that we could always diagnosticate each of the several forms of Bright's disease, or that it was essential to do so, but he did desire to have it understood that, the more clearly the pathological condition and its relations to disease in other parts of the body was appreciated, the better would the physician be prepared to treat it. Attention should also be directed to predisposing diathesis, as the rheumatic and phthisical. The writer mentioned appropriate treatment for special symptoms, and, speaking of pilocarpin as having restored to life patients buried in profound coma, stated that, in some instances, it had produced most alarming syncope. The successful treatment of Bright's disease, he concluded, called for many kinds of remedial measures, and experience, in any given case, might have to be relied on to determine what might be the best measure.

Dr. A. Jacobi thought the paper had stated in very few words all that could be rationally said on the subject, provided one was satisfied with a few words which hit the mark. He believed the treatment given by the author was more or less that of all rational physicians of to-day. Dr. Delafield was a little better off than Dr. Satterthwaite because his divisions and subdivisions of Bright's disease were so much simpler than the seven or nine made by Dr. Satterthwaite.

Agreeing with the author in most respects as to treatment, Dr. Jacobi stated a few points wherein he differed, and, thinking Dr. Delafield had recommended caffein as a heart tonic in connection with uræmia, he said that in his experience coffee and caffein had bad effects in cerebral hyperæmia, whether passive or active. Leeches applied to the septum nares had recently shortly relieved a woman from uræmic coma of unknown origin, while he was confident caffein would have made her condition worse.

Regarding bichloride of mercury, he had used it a number of years in all cases of chronic interstitial inflam mation in different organs, administered in small doses for months. It was of equal benefit in interstitial inflammations of the kidneys, but rather of the chronic kind.

Dr. Jacobi thought physicians would be more successful in the treatment of acute and subacute nephritis if they were to look for it more commonly than they did. It occurred not alone in nephritis, but often also after measles, and especially after typhoid fever, and also after other acute diseases, and would be found much more remediable if taken early. That form of nephritis seen in men after the fortieth or fiftieth year, the result of vascular degeneration, had been benefited in his experience by adding bromides to the general treatment. He believed digitalis should be avoided early in acute nephritis, as it acted as an irritant on the kidneys. Where a cardiac stimulant was desired which did not act as a kidney irritant, he gave sparteine, which was absorbed and eliminated readily, and produced no cumulative effects.

Dr. F. P. Kinnicutt said that he had little to add to the suggestions contained in Dr. Delafield's paper. Fortunately, in the larger proportion of cases of acute nephritis occurring after exposure to cold or infectious diseases, there was a marked tendency to self-limitation and spontaneous recovery. Hence in many cases simple confinement to bed, with external warmth and a milk-diet, constituted the indicated treatment.

He could heartily endorse Dr. Delafield's views in regard to the desirability of principally concentrating our attention upon the inflammation of the kidney and the disturbances of the circulation.

It was well to bear in mind, in connection with the circulatory disturbances, the not very infrequent occurrence of sudden death from heart failure, in cases of acute nephritis, the usual symptoms of uræmia being wholly absent. A series of such cases, occurring in children suffering from acute nephritis, had been published by Dr. Goodhart, of Guy's Hospital. Great dilatation of the left ventricle, without valvular disease, was found to exist. The explanation was not far to seek. A heart, whose nutrition had suffered presumably from the disease, had suddenly dilated from the increased amount of work thrown upon it by arteries obstructed by spasm or changes in their coats, or both. In cases where evidence of cardiac failure from high arterial tension existed, heart stimulants, combined with means to relieve tension, were plainly indicated. Dr. Kinnicutt was in the habit of relying upon those cardiac stimulants which acted upon the heart without, at the same time, increasing the contraction of the vessels, viz., strophanthus and the sulphate of sparteine. To relieve arterial tension, he preferred the pure vaso-motor dilators to some of the drugs mentioned by Dr. Delafield. Among the vaso-dilators the nitrites ranked first, and of these, nitro-glycerine was in most common use. He was convinced, from practical experience, that nitro-glycerine, given in sufficiently large and frequently repeated doses, was a most potent means of reducing arterial tension. On theoretical grounds, digitalis was contraindicated in cases of threatening heart failure from arterial tension. It caused contraction of the small arteries at the same time that it increased ventricular contraction.

Dr. J. West Roosevelt thought that in the treatment of subacute nephritis, as the author had stated, there were

a good many indications. There were cases in which the high arterial tension was in itself a source of danger, and demanded relief. Though arterial tension was generally regarded as dangerous, the reasons for such danger were not, it seemed, commonly understood. Except for the danger to the heart from overwork, or to the vessels on account of changes in their walls in old cases, there was no direct danger from arterial tension. The indirect harm came from obstruction to the capillary circulation, owing to contraction of the arterioles. There being a spasmodic condition of the arterioles and capillaries more blood could, perhaps, be forced through by administering digitalis, but that seemed to him a very clumsy way to accomplish the purpose. The digitalis must produce the result by forcing an already strained heart to do more work. The use of vaso-motor dilators, among which he included chloral, would seem more rational. But this was a passing makeshift to carry the patient beyond a certain danger-point. Real treatment consisted in re-establishing the functions of the kidneys as far as possible.

He was glad to hear Dr. Delafield make the statement that uræmia, manifested in the form of coma and convulsions, was to be feared in acute cases only during the earlier days, while patients who lived longer passed into a typhoid state and died, not in what ordinarily was called a uræmic condition. It had always seemed to him unfortunate that the idea should become firmly fixed in the mind of the profession that uræmia necessarily followed interference with renal function. As a matter of fact, it might not be manifest in total suppression of the urine of some days' duration. Clinically he had found two sets of uræmic cases: (1) Those with coma and convulsions accompanied by marked increased arterial tension, and here nitro-glycerine and nitrites were indicated; (2) those in which patients suddenly became comatose, in whom there was no increased tension. Here it might be necessary to stimulate the heart.

Dr. Joseph E. Winters had observed that in subacute cases exercise caused an increased amount of albumen in the urine, and the amount of albumen in the urine he thought was the best indication as to the condition of the patient. Therefore in recent subacute cases the same rule should apply as in acute cases, to place the patient in bed and regulate the diet so as to decrease the amount of albumen. Especial attention should be paid to the function of the skin, and the food should not contain much of the albuminoids. Milk, fish, and fats, as cod-liver oil, were indicated. While he always used iron in subacute nephritis, as was the fashion, yet he doubted whether in such cases it had the good effect seen in anæmia from other causes. He had observed that patients who had other indications of a severe attack and had free effusion into the skin were less likely to have nervous symptoms, or to suffer from uræmia, than those who had no œdema. Perhaps it was because a part of the urea which the kidneys failed to excrete filtered into the cellular tissue and there proved less harmful.

Dr. Laurence Johnson said that, attention having been directed more particularly to the dangers connected with the use of pilocarpin, he wished to give his experience with its good effects in uræmic poisoning. He had used it for several years, and had had most beneficial results accrue in a short time in cases of coma and convulsions. He thought there was little danger in its use on strong patients. He gave hypodermatically one-sixth of a grain of hydrochlorate of pilocarpin, repeated in fifteen and again in twenty minutes, and a fourth time after two hours and a half, sometimes running up altogether to one grain.

The President thought the physician, when brought face to face with acute or subacute nephritis, should first take into consideration the age, the predispositions, and the habits of his patient. The management of a case in a child would evidently differ from the management of a case in an adult. In acute Bright's disease, as a rule, the treatment should be rest in bed in an even temperature, regulation of the diet, and moderate purgation. If there were convulsions and nervous symptoms due to accumulation of excrementitious products, something more would need be done. If there were high arterial tension in young subjects, the cardiac tonics spoken of during the discussion were contraindicated. The arterial tension should be reduced by drugs acting on the vaso-motor system. Dr. Delafield had mentioned mercury and the salines. In his own experience calomel in small doses at short intervals, accompanied by the free use of salines, best reduced arterial tension. These measures, with the addition of counter-irritation over the kidneys and stimulation of the surface of the body, would, in all probability, bring about a good result unless in patients reduced by special circumstances, such as the alcoholic habit.

In subacute nephritis there was a different condition, and it called for different management. If he had become more positive on one point than on another in the treatment of these cases it was that they should not be depleted. All those means should be brought into service which improved nutrition. Iron, as far as he could judge, was of little use. Change of climate was important. If the urine was diminished in quantity, and there was heart failure, digitalis was indicated only as long as it had the effect of increasing the urinary excretion; when it ceased to have this effect it would do harm. It was contraindicated in high arterial tension. Where there was a weakened heart, from accumulation of poison in the system, nothing equalled small doses of opium given regularly for an indefinite length of time.

Dr. Delafield, in closing the discussion, corrected Dr. Jacobi's impression as to his recommending caffein; he had only stated that it was recommended in the French "Dictionary of Medicine." Bichloride of mercury was an old stand-by in subacute nephritis; but he was unable, inasmuch as other remedies were employed at the same time, to tell just how much benefit could be attributed to its use. Dr. Jacobi had called attention to an important fact, namely, that subacute nephritis occurred much more frequently than was supposed. As to the relief of arterial tension, the method differed decidedly in acute from that in subacute nephritis. In the former, nothing relieved the arterial tension so quickly as small doses of sulphate of magnesia or calomel given in small doses only until the bowels began to move. The drug was not given for the purpose of purging the patient. Its administration was empirical, as it was in acute peritonitis. Having thus reduced the arterial tension, it could best be maintained by aconite. But in subacute nephritis calomel and sulphate of magnesia did not reduce arterial tension; there it was necessary to give a drug which dilated the arteries, which might be, according to the individual case, nitroglycerine, chloral hydrate, etc. In low arterial tension in subacute nephritis, the indications for digitalis were such as had been pointed out by Dr. Loomis.

He did not agree with Dr. Winters in the view that the amount of albumen in the urine was the chief indication as to the progress of the case. It was only one of several indications of as much importance. He also differed from him in the view that the feeding should be regulated with reference to the amount of albumen in the urine. As to iron apparently producing no results in anæmia from subacute nephritis, it might not be manifest in the diminution of the dropsy nor as regarded the quantity of urine, but examination of the blood might show an increased amount of red blood-cells and hæmoglobin, and thus an improved state.

The President impressed upon the Fellows the necessity for individual effort in raising the additional twenty-five thousand dollars required to complete the purchase of the site and put up a new building in Forty-third Street.

He also said that if it was the desire of the members to continue the hour of meeting at eight o'clock, they must arrive at that time; if they could not come until half-past, then the hour of meeting should be changed to accord.

OUR LONDON LETTER.

(From our Special Correspondent.)

COLECTOMY VS. COLOTOMY IN MALIGNANT DISEASE OF THE INTESTINE—THE COLLEGE OF SURGEONS AND ITS CUSTODIANS—THE POLICY OF THE BRITISH MEDICAL JOURNAL—FURTHER DISCIPLINARY POWERS FOR MEDICAL AUTHORITIES—GOVERNMENT GRANTS IN AID OF HIGHER SCIENTIFIC EDUCATION—THE ZANDER INSTITUTION.

LONDON, March 5, 1889.

JUDGING by the steady increase in the number of operations on record, it might be thought that colectomy was growing in favor as an operative measure in malignant disease. Anyone, however, who, having formed this opinion, had attended the last meeting of the Medical and Chirurgical Society, would probably have come away with somewhat altered views—that is, if he were disposed to accept the general tenor of the discussion as fairly representative of surgical opinion on the subject. The operation was then condemned by some even of those who had practised it.

Dr. Kendal Franks, of Dublin, read an elaborate paper in which he described two cases of his own and gave a summary of fifty-one published cases. In forty per cent. of these the operation had proved fatal. One of Dr. Franks' own cases terminated fatally, but the other was most successful. It was that of a man, fifty-eight years of age, who was admitted into hospital suffering from dyspeptic symptoms and diarrhœa; a remarkably movable tumor was found in the abdomen in the middle line below the umbilicus. Abdominal section was performed, and the tumor was found to be an epithelioma surrounding the transverse colon near the hepatic flexure. The bowel was divided on each side of the tumor and the latter then removed, together with several enlarged glands found between the layers of the meso-colon. The divided ends of intestine were sutured together and returned to the abdominal cavity. On the sixth day there was a copious motion *per anum*, and the bowels acted regularly afterward. The patient was now—four months after the operation—in very good health, and had increased in weight. While admitting that colectomy rarely effected a cure, the author nevertheless urged that it was justifiable as a palliative measure, and frequently demanded. Even when the growth recurred, it usually did so in the liver or mesenteric glands, and death was then much easier than when the intestine was occluded. The mortality after immediate suture of the intestine and after the formation of an artificial anus was nearly equal, but the former procedure was preferable. Dr. Franks pointed out that the death-rate had been reduced in the later cases, and that a further reduction might be anticipated.

Mr. Bryant then spoke, and said his feeling was against the operation. Only one case out of fifty-one had resulted in a cure, and as a palliative measure he gave the preference to colotomy. The latter operation not only gave complete relief, but death occurred comparatively painlessly from asthenia from secondary growths. Patients lived for four, five, or six years after the operation; certainly three or four years might be looked for if the operation were done before urgent symptoms of obstruction arose.

Mr. Treves followed, and did not express a much more favorable opinion. He congratulated Dr. Kendal Franks on his brilliant operations, but, while thanking him for his collection of cases, remarked that he considered it to be the death warrant of the operation. Intestinal cancer grew rapidly in a region so abundantly supplied with vessels and lymphatics. If the cancer attacked the ascending or the descending colon, it was practically impossible to take out the whole of the disease; in the mid-region of the colon it was only just possible. Colectomy was at best a plastic operation, and that was one very ill-adapted to a cancerous patient. He had himself brought forward a case six years ago, but since then he had never seen a case, and he expected he never should see a case in which he should have any idea of resecting the bowel again. He thought the operation compared badly with lumbar colotomy.

Mr. Bernard Pitts was somewhat more hopeful. He remarked that cancer of the bowel lent itself to removal as easily as in other parts; the difficulty was to get the cases early enough.

Dr. Kendal Franks then replied in defence of the operation. Though colotomy was the best operation for rectal cancer, he could not admit that it was better than colectomy for many other cases of intestinal cancer; it was admittedly only palliative. He predicted that with more practice in abdominal surgery colectomy would become commoner, and said he regarded his collection of cases as rather the herald than the death-warrant of the operation.

Who shall decide when doctors disagree? Such might fairly have been the question of an outsider on beholding the scene outside the College of Surgeons on Thursday last. The authorities of the College not only shut the doors to keep out their own Members and Fellows, but added insult to injury by having obtained the services of the police to protect the building from any threatened attack. Did the Council imagine that professional men would act like roughs? Balked of their intention of meeting in their own College, the assembled Fellows and Members betook themselves to an adjoining restaurant, where it was decided to bring the long-standing grievances of the Fellows and Members of the College before Parliament—a draft bill on the subject being presented. Earlier in the day an application was made in the law courts for an injunction to prevent the Council from closing the College. This proved unsuccessful. I understand, however, that the questions of law involved will come before the courts at once, so the battle will be both legal and parliamentary.

A protest against the manner in which the *British Medical Journal* is conducted has been drawn up and is being extensively circulated. It has already been signed by many influential members of the profession. The "Mackenzie-Bergmann" controversy and the action of the *Journal* in relation thereto has led up to the present procedure.

The General Medical Council are promoting a bill to give further disciplinary powers to the different medical authorities to withdraw, or restore, the various qualifications granted by them. A bill for this purpose has been drawn up by the legal advisers of the Council at the request of the president, and will in due course come before the Council for consideration.

It is reported that the Government has decided to make a grant in aid of higher scientific education, and that King's and University Colleges (which are also medical schools) will participate in the grant.

An unfortunate misprint occurs in the "London Letter" in your issue of February 23d. "Lander Institution" should read "Zander Institution," being named after Dr. Zander, with whose name many of your readers are doubtless acquainted.

PRENATAL CIRCUMCISION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In THE MEDICAL RECORD of November 3, 1888, page 535, I reported a case of circumcision by maternal impression.

In THE MEDICAL RECORD of December 15, 1888, Dr. M. G. Lowrey, of Boulder, Col., thinks the case of so much importance to the profession that it should be established beyond question. I therefore enclose the certificate of Dr. R. Tobey, who assisted me in the operation and afterward attended the mother in confinement.

I do not propose to account for the phenomenon on a

scientific basis, but can furnish the doctor and the professor with indisputable evidence as to the facts.

J. G. HARVEY, A.M., M.D.

BLUE MOUND, ILL., February 12, 1889.

(*Copy.*)

I hereby certify that I assisted Dr. Harvey in circumcising the son of Mr. S—— as reported in THE MEDICAL RECORD of November 3, 1888, and that I attended his mother in confinement on March 31, 1885, just seven months and twenty days after the operation, at which time she was delivered of a male child, which was perfectly circumcised, and presented exactly the appearance of having been circumcised in the same manner as the boy previously operated upon, even showing the marks of each suture.

R. TOBEY, M.D.

MACON, ILL., February 10, 1889.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 10 to March 16, 1889.

BAXTER, JEDEDIAH H., Colonel and Chief Medical Purveyor. By direction of the Secretary of War, will proceed to New York City on public business connected with the Medical Department, and on completion thereof return to his station in this city. Par. 18, S. O. 57, A. G. O., Washington, D. C., March 11, 1889.

GREENLEAF, CHARLES R., Major and Surgeon. Is appointed member of Board to meet in this city, on March 11, 1889, for the purpose of revising the blank forms now in use in the Army, and preparing the "Book of Forms" for issue. Par. 13, S. O. 55, A. G. O., Washington, D. C., March 8, 1889.

SHUFELDT, ROBERT W., Captain and Assistant Surgeon, By direction of the Secretary of War, having been found incapacitated for active service by an Army Retiring Board, is granted leave of absence until further orders, on account of disability. Par. 7, S. O. 56, A. G. O., Washington, D. C., March 9, 1889.

JOHNSON, RICHARD W., Captain and Assistant Surgeon. By direction of the Secretary of War, is relieved from duty at San Carlos, Ariz., and will report in person to the commanding officer, Whipple Barracks, Ariz., for duty at that station. Par. 15, S. O. 57, A. G. O., Washington, D. C., March 11, 1889.

Official List of Changes in the Medical Corps of the United States Navy for the week ending March 16, 1889.

HESLER, FREDERICK A., Assistant Surgeon. Detached from Naval Hospital, New York, and ordered for examination preliminary to promotion.

OGDEN, FREDERICK N., Assistant Surgeon. Ordered to Receiving-ship St. Louis, Navy Yard, League Island.

BRYANT, PATRICK H., Assistant Surgeon. Detached from Receiving-ship St. Louis, and to the Naval Hospital, Chelsea, Mass.

Medical Items.

THE LATE DR. JOHN C. DALTON.—At a special meeting of the Trustees of the College of Physicians and Surgeons in the city of New York, held February 26, 1889, the following minute was adopted, and ordered to be entered on the records of the Board:

"The Trustees of the College of Physicians and Surgeons desire to express their deep sense of the loss sustained by the College in the death of its President, Dr. John Call Dalton. During the thirty-four years of his connection with the College, first as Professor of Physiology and afterward as President, Dr. Dalton took a warm interest in all that concerned the welfare of the institution. The College was, in a special and peculiar sense, his real home. A large portion of his daily life was spent within its walls, and here was accomplished most of the work which rightly placed him in the front rank of American physiologists. Although a man of broad sympathies which carried him into other departments of science, and into questions of public affairs, his life was centred here, and nothing lay so near his heart as the College of Physicians and Surgeons, its best interests, and its advancement to a higher plane of professional education. As a teacher, Dr. Dalton possessed qualifications of the highest order. He was always master of his subject; while, by a seeming paradox, his subject mastered him. There was, for this reason, a certain contagiousness in his absorbing interest in his theme. Even the dullest facts, under his treatment of them, acquired a new freshness, either by some original illustration, some presentation from an unusual standpoint, or by a quaintness of expression that gave them an air of novelty. But nothing displayed so well his rare genius in imparting knowledge as the skill with which he simplified the most difficult subject by the orderly arrangement of its principles, and the transparent clearness of his language. To this directness and simplicity of speech, which was typical of the whole character of the man, was joined a peculiar charm of manner that fascinated everyone who came in contact with him. With children he was a great favorite. From him an explanation of the mechanism of some familiar object, or a story of natural history, told in his inimitable way, brought greater delight to the child at his knee than the most exciting fairy tale from anyone else. And so in the lecture-room, although Dr. Dalton had none of the more conspicuous but commonplace gifts of oratory, there was a certain personal magnetism about him—a rare, subtile quality of vital power, that at once placed him in sympathy with his audience and gave him absolute control over it. To the office of President Dr. Dalton brought a practical knowledge of men and affairs, a love of work, and thoroughness in it, that qualified him for the position to a degree that now seems almost providential. During his busy administration the College was removed to its present situation, its new buildings were erected, and its curriculum enlarged. Out of these changes grew a host of difficulties, many of them of an entirely novel character, which could be solved only by the exercise of the soundest judgment and the most laborious attention to details. Dr. Dalton approached this task in a conscientious spirit, determined that the trust imposed by the generous benefactors of the College should be carried out faithfully. With health already impaired by the disease of which he died, his labors were indefatigable. He seemed to feel that the time was short; but when the end came, he had the satisfaction of knowing that his work had not been in vain. The ambition of his later years was realized. He had lived to see the College he loved with a more than filial affection entering with bright prospects upon a new era of prosperity. Could he have known, also, with what a fulness of gratitude his unselfish labors were regarded by all of the alumni and officers of the College, who can doubt that even his well-merited scientific honors would have had less value to him in his dying hour than such a tribute to his personal character?—GEORGE G. WHEELOCK, M.D., *Registrar.*"

THE EXCITING CAUSE OF URTICARIA.—Dr. Jacquet regards local irritation as the exciting cause of the pruritus and wheals of urticaria, the underlying cause being an abnormal condition of the cutaneous vaso-motor nerves. He has found that, by hermetically covering any portion of the body in a case of generalized urticaria, the pruritus and wheals almost immediately disappear from that part, the uncovered surface remaining unchanged.

KOCHER'S METHOD OF REDUCING SUBCORACOID DISLOCATIONS OF THE HUMERUS—A PLEA FOR ITS EMPLOYMENT IN EVERY RECENT CASE.[1]

BY CHARLES A. POWERS, M.D.,

SURGEON TO OUT-PATIENT DEPARTMENT, NEW YORK HOSPITAL.

CONSIDERATION of the various forms of the luxations which occur at the shoulder-joint, their causation, mechanism, pathology, and immediate and subsequent treatment, is without the scope of this brief paper. In the few moments which are at my disposal I shall call your attention to but one point, the reduction of the subcoracoid form by the method known as "Kocher's."

And I venture to assert that there is no surgical procedure of equal simplicity and of like importance as little known to the profession of our country as is this.

In the *Berliner Klinische Wochenschrift* for February, 1870, Professor Theodor Kocher, of Berne, first published the results of his cadaveric researches regarding the mechanism of this dislocation, and gave to the profession the most logical, scientific, and successful plan for its reduction which has yet been presented.

His theory is that the end to be attained in attempts at reduction is to open the rent in the capsule and to relax its intact portions without employing force.

When the head of the bone passes from the glenoid cavity to beneath the coracoid process it rends the capsule at its inner and lower part. The rent extends to the insertion of the tendon of the subscapularis, lacerating some of the fibres of that structure.

Tension in the capsule is greatest at its upper part, between the tendon of the long head of the biceps and the upper border of the subscapularis.

The posterior portion of the capsule and the tendons which reinforce it are preserved and stretched across the glenoid cavity. At the point of greatest tension the capsule is reinforced by the coraco-humeral ligament.

When, in a given case of subcoracoid luxation, the arm is adducted and strongly rotated out, the rent in the capsular ligament will be freely opened; but as the upper and lower parts of the capsule are yet tense the head of the bone remains firmly fixed against the anterior edge of the glenoid cavity. If, however, the arm is brought forward and upward across the chest, the upper part of the capsule relaxes; but the lower part, being yet tense, serves as a fixed point about which the head of the bone revolves and thus slips into its cavity.

Professor Kocher turned this anatomical knowledge to account in formulating the following procedure[2] for the reduction of a humerus, the head of which rests beneath the coracoid process.

Suppose the right shoulder to be the seat of the injury. The patient is seated and the surgeon kneels beside him. With his left hand he grasps the arm of the patient just above the elbow. The patient's forearm being flexed to a right angle, the surgeon firmly seizes the wrist with his right hand. Then adducting the elbow to the body he utilizes the lever furnished by the forearm and rotates the arm out until firm resistance is met (practically until the forearm makes an angle of ninety degrees with the antero-posterior plane of the body). Now, with the arm still strongly rotated out, he brings the elbow forward and upward in the sagittal plane across the chest, and finally rotates the arm in, and places the patient's hand on, his opposite shoulder.

This procedure I would amend by placing the patient squarely on his back, with both shoulders resting on a firm table, and as there is a great tendency for him to turn his body to the affected side during the external rotation of the arm, I think it well that the opposite shoulder be held down. This may be done by a bystander. It is well, also, that downward traction[1] be added to adduction of the elbow in the first movement.

The manipulation is shown in Figs. 1, 2, 3, and 4. I am indebted to Dr. C. C. Page, assistant at the Chambers Street Hospital, and to my pupil, Mr. T. B. Enders, for their kind assistance in the matter of the illustrations.

The following case will serve as an example: A muscular porter, aged twenty-six, presented himself at the Chambers Street Hospital with the history of having fallen forcibly on the external aspect of the right shoulder twenty minutes previously, the arm being at the time of injury abducted to about seventy-five degrees.

Examination revealed a typical subcoracoid dislocation of the right arm. There was the usual prominence of the acromion with a hollow beneath it, the head of the humerus was both seen and felt beneath the coracoid process of the scapula. The elbow was abducted thirty degrees from the body. The affected arm was about one-eighth of an inch shorter than its fellow. No fracture could be detected. The patient having well relaxed his muscles, Kocher's procedure was employed as above described. As the arm underwent external rotation the contour of the shoulder became fuller, and at the beginning of the third movement (sweeping the elbow forward across the chest with the arm still in external rotation—Fig. 3) a distinct crackling sound was heard and the head easily slipped into the glenoid fossa. The patient said that he experienced very little pain. The crackling sound, of which mention is made, is very often heard as the head goes back. It has been thought by some writers to be due to a progressive laceration of the capsule, but this I think incorrect, for it does not occur while the capsule is at its greatest tension. I think it simply bony crepitation produced by the slipping of the head of the humerus across the anterior margin of the glenoid fossa.

In a later article[2] Professor Kocher lays additional stress on the importance of the coraco-humeral ligament, and, likening it to the ilio-femoral ligament of the hip-joint, says that the subcoracoid dislocation at the shoulder corresponds to the obturator dislocation at the hip.

In a minute description of the coraco-humeral ligament he says that it assumes the form of an inverted Y, the outer limb of which is a strong, tense band of fibres passing between the upper part of the glenoid fossa and the greater tuberosity. (It has heretofore been confounded with the tendon of the supraspinatus, which stretches

---

[1] Read before the Medical Society of the State of New York, at its Eighty-third Annual Meeting, February 6, 1889.

[2] This procedure Kocher mo estly calls a modification of Schinzinger's, but it differs in a most important particular. The first two movements are alike in both, but at the end of external rotation (second movement) Schinzinger has an assistant draw the head of the bone into its place by means of a fillet, or he grasps and forcibly presses it outward.

[1] Jersey: New York Medical Journal, September, 1883.

[2] Volkmann's Sammlung klinischer Vorträge Chirurgie, 1-28.

across this part of the capsule.) The tension of this outer limb "wedges in" the head of the humerus beneath the coracoid process. The other part of the Y runs to the lesser tuberosity and the adjacent capsule. Fibres pass between them which correspond to the zona orbicularis at the hip.

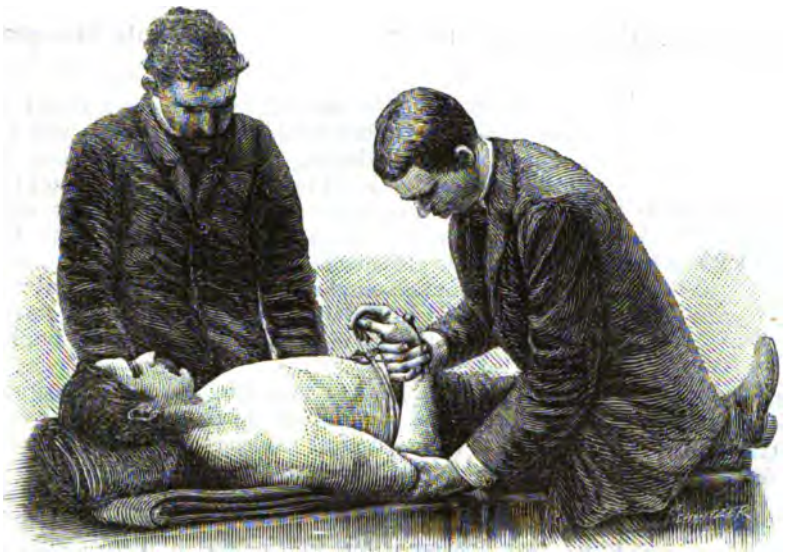

FIG. 1.—First Movement. The elbow is adducted to the body and drawn downward. (The arm and wrist should be firmly grasped, as shown in the figure.)

The internal limb is the stronger, and limits external rotation.

Professor Kocher says that when the coraco-humeral ligament is ruptured, or the anterior portion of the capsule severely torn, the procedure fails because the humerus loses the fixed point about which it should revolve.

Faraboeuf,[1] however, has come to a conclusion diametrically the opposite of this. He proved upon the cadaver, and showed to the Surgical Society of Paris, that though all of the anterior ligaments be cut the procedure succeeds; but when the posterior portion of the capsule is divided the head simply revolves in external rotation but fails to enter its normal cavity. He contends that the success of Kocher's procedure is due to the integrity of the posterior portion of the capsule. That when the first movement, or adduction, is made, this portion is made tense. That in the second movement the head is turned outward around the lower fixed point of the ligament, and in the third movement it simply undergoes an external excursion through the rent at the inner part of the capsule and into the glenoid cavity.

Through the courtesy and with the assistance of Dr. George B. Phelps, Jr., Demonstrator of Anatomy at the Woman's Medical College, experiments were made upon the cadaver, with a view to proving the correctness of one or the other of these assertions.

Upon one shoulder we divided subcutaneously the capsule at its inner and lower part, and threw the head of the humerus beneath the coracoid process. Kocher's procedure easily replaced it. We then cut the coraco-humeral ligament and the anterior part of the capsule, but employment of the procedure was equally successful in reducing the dislocation. Upon another shoulder the posterior part of the capsule was divided, after the head of the bone had been dislocated forward, yet it was replaced by Kocher's manœuvre as easily as were the others. It was only after the capsule had been almost completely divided that external rotation failed to meet with resistance.

Through lack of time but few experiments were made, and their results are unsatisfactory and inconclusive. I hope in the near future to make an additional communication upon this interesting point.

In the article above referred to in "Volkmann's Sammlung," Professor Kocher states that since his original paper he has adopted the procedure in thirteen cases, in eleven of which reduction was easily effected and without the aid of an anæsthetic. In a still later article [1] he places added emphasis on the value of the manipulation, and avers that it is applicable to old cases as well as to those of recent date. In the original paper he contended that it was inapplicable to the intracoracoid cases (the subclavicular of English writers); but he now states that it does succeed in these if the elbow be adducted in the posterior axillary line during the first movement.

Ceppi [2] concludes that all known methods for the reduction of this luxation are inferior to that of Professor Kocher, and in a later article [3] says that further experience only strengthens this opinion.

Kaufmann [4] says that when correctly applied the method is always successful, and that without the aid of an anæsthetic. He cites eleven cases reduced by him.

Carafi [5] says, "thanks to the method of Kocher, the reduction of recent subcoracoid dislocations is now one of the simplest procedures in practical surgery." He had used it with success in twenty cases, and recommends that in the subclavicular cases the arm be held for two or three moments in the position of external rotation.

Davezac [6] employed it with success in several instances and recommends that it be applied to every recent case.

FIG. 2.—Second Movement. The arm is rotated out until firm resistance is met. (Practically until the long axis of the forearm points directly outward.)

Poinsot,[7] Perrier,[8] and Ferron,[9] strongly endorse the method, but add nothing of moment.

Mr. C. Heath [10] relates five cases occurring in his ser-

vice at the University College Hospital, in three of which the bone was replaced at the first attempt and without ether. while, in the other two an anæsthetic was given.

Mr. Pick[1] considers the plan the simplest for the reduction of shoulder dislocations, but incorrectly states that it is applicable to the subglenoid variety as well as to the subcoracoid.

All writers agree that the procedure fails when the capsule is severely torn, and in support of this permit me to cite to you the following case :

A muscular man, twenty-eight years of age, sought treatment at the Chambers Street Hospital, January 28, 1889, with a history of having recently had the left shoulder caught between an elevator and a beam, and subjected to severe pressure, the arm at the time being abducted. The shoulder was the seat of a typical subcoracoid dislocation. Kocher's method was tried, but was unsuccessful. During the second movement (external rotation) no resistance was met. The method also failed under ether, and the arm was replaced by direct traction at a right angle.

The lack of resistance during external rotation seems very good evidence of severe injury to the capsule.

Its Employment at the Chambers Street Hospital, New York.—Early in 1883 a description of the method came under the notice of Dr. William T. Bull the Attending Surgeon to the Hospital, and under his direction its employment was begun. The first case was that of a man, seventy years of age, who presented himself at the hospital March 3, 1883. His subcoracoid humerus was so quickly and easily replaced in its normal cavity that surprise and delight found place in the minds of all who observed the procedure. Since then the method has been used to the exclusion of all others. The results in the first six months were published by Dr. Charles A. Jersey, in the *New York Medical Journal* for September 23, 1883, in an article entitled, "Twenty-one Cases of Subcoracoid Dislocation of the Humerus reduced by Kocher's Method." In seventeen of the twenty-one cases the reduction was effected at the first attempt, in the other four the bone went back at the second, third, fourth, or fifth attempt, respectively. In none was an anæsthetic used.

During the five years ending with October 1, 1888 (the five years following the publication of Jersey's paper), 173 recorded cases of recently dislocated humerus find place in the history books of the Chambers Street Hospital. Of these, 44 were subglenoid and 129 subcoracoid.

[1] Fractures and Dislocations p. 375.

The results of treatment in the subcoracoid cases are as follows :

Without ether, Kocher's manipulation, successful at first attempt	98
Without ether, Kocher's manipulation, successful at second attempt	6
Without ether, Kocher's manipulation, successful at third attempt	8
Without ether, Kocher's manipulation, successful at fourth attempt	1
Failed without ether, with ether successful at first attempt	6
" " " traction at a right angle, successful	5
" " " foot in axilla, successful	1
" " " the head undergoing extreme external rotation [1] slips into axilla and is then reduced as axillary	1
Kocher not tried, success by traction at a right angle	3
	129

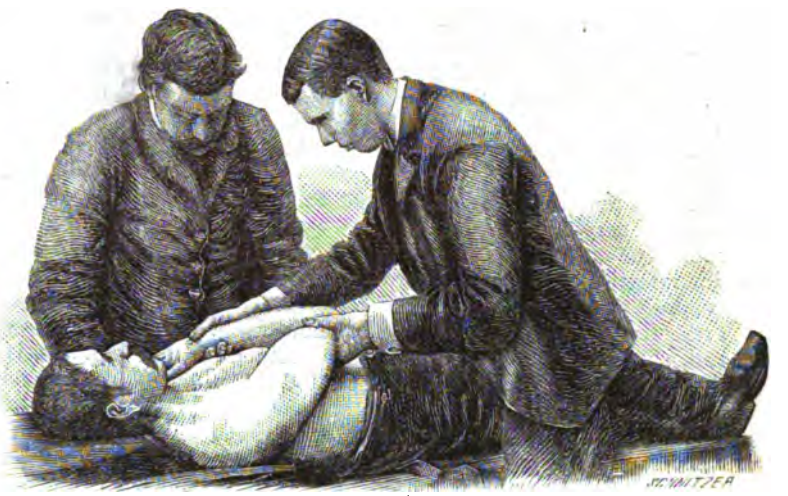

FIG. 4.—Fourth Movement. The hand is placed on the sound shoulder.

We thus see that of the 126 cases in which the procedure was resorted to it was successful in 98 cases, or 77 + per cent., at the first attempt, and that without the aid of an anæsthetic. Let us, however, make due allowance for the fact that these dislocations were reduced by some twenty-five different gentlemen, each of whom numbered in this list his "first case," on which, perhaps, he failed at first attempt.

Let us assume, moreover, that the list is not entirely free from diagnostic errors, and that more than one case which is classed as subcoracoid, was, in reality, an axillary luxation.

From the personal reduction of a not inconsiderable number of these cases, and the observation of many more, I am fully prepared to share the opinion of the authors to whom I have referred, that "in a recent simple case, the manipulation should prove successful at the first attempt, without anæsthesia."

In none of these cases was an injury inflicted on the axillary vessels or nerves.

Recital of them would be devoid of interest. Most of them occurred in muscular laborers ;[2] many of the patients presented themselves in a state of intoxication, and either strenuously resisted manipulation, or absolutely refused it without the influence of an anæsthetic. These considerations aid in accounting for the "first-attempt" failures, for those cases in which ether was given.

Causes of Failure.—1. Muscular rigidity. 2. Extensively torn capsule. 3. Fracture complicating the dislo-

FIG. 3.—Third Movement. With the external rotation of the arm still maintained, the elbow is carried forward and upward on the chest.

[1] Doubtless a case in which the capsule was severely torn.

[2] It seems unnecessary to call attention to the patent fact, that before attempting the reduction of any dislocation the patient's muscles should be thoroughly relaxed. In ignorant or frightened subjects this is often difficult of attainment.

cation. 4. Error in diagnosis. 5. Failure to properly adduct the elbow, or to sufficiently rotate the arm out. 6. Inward rotation of the arm before completion of the third movement. 7. Dislocation of such long standing that adhesions have formed about the head and neck of the bone.

Conclusions.—1st. Of the various luxations which the humerus undergoes the subcoracoid is much the most common.

2d. The method to be employed in its reduction is, *par excellence*, that of Kocher, and it should be used in every recent case.

3d. The procedure is logical and safe. It may easily and rapidly be carried out. Its careful, accurate, and thorough employment will almost invariably assure success at the first attempt.

4th. It will not succeed in those cases, happily uncommon, in which the capsular ligament is severely torn.

5th. The patient should be in the dorsal position.

6th. An anæsthetic is unnecessary.

7th. The aid of a skilled assistant may be dispensed with. It is advisable that the opposite shoulder be steadied, but this can be done by a layman.

8th. It is attended with the least possible pain to the patient.

9th. It is practically without danger to the important vessels and nerves.

10th. The question as to whether its success depends on the integrity of the anterior or of the posterior part of the capsule must yet be considered *sub judice.*

11th. It rarely succeeds in the subglenoid form.

12th. It is applicable to the intracoracoid cases, but in those the elbow should be placed behind the posterior axillary line (Kocher) and external rotation should be maintained for two or three minutes (Carafi).

13th. In all cases in which much resistance is met with during the early part of the second movement the position of external rotation should be steadily maintained for a short period before bringing the arm forward and across the chest.

18 East Twenty-fourth Street.

CONSIDERATIONS CONCERNING EXTRACTION OF HARD CATARACT, WITH AN ANALYSIS OF THREE HUNDRED AND NINE CASES.

By HENRY D. NOYES, M.D.,

NEW YORK.

The topics to be considered in this paper relate to: 1st, the suitableness of a cataract for operation; 2d, the method of operating, with its attendant performances and possible accidents; 3d, the events of the healing process; 4th, the visual results; 5th, secondary operations.

The opinions and deductions are founded upon my own experience, while the statistics presented are partly my own and partly those of my colleagues in the New York Eye and Ear Infirmary. I have chosen to gather the results of operations by several surgeons, in order to present what may justly be assumed to be the work of those who have the ordinary and competent degree of experience and skill. In this regard, it appears to me, carefully analyzed results have special value, as showing what is attainable by an average measure of trained ability, conceding, of course, that the highest possible skill could reach results of better quality. Moreover, the results in a public institution, whose arrangements and construction are not what the strict demands of hygiene, as now understood, call for, must, of course, be inferior to what would be attainable under more perfect discipline, management, and construction, especially when a hospital is under control of a single intelligent head. It is premised that among the eight operators whose work upon 309 cases, between October, 1884, and January, 1889, is presented, none are included who have contributed less than twenty operations, which is about one-fifteenth of the whole, and the highest contribution of a single operator is one-fourth of the whole.

1st. What constitutes the fitness of a cataract for operation is not yet fully agreed upon. It is widely held and taught that so long as any sight remains no operation should be done. In a general way this is true. But I wish to call attention to certain cases to which this rule does not apply. They are those in which the hardening or sclerosis of the lens extends beyond the middle parts, or so-called nucleus, to the cortical layers, and these do not suffer the fissuring and disintegration which constitute ordinary cortical opacity. Instead of the white and striated look of ordinary cataracts, such lenses appear dull, smoky, deeply yellow; when of very long duration, say six or more years, they become reddish by reflected light, and even black. Vision is greatly impaired, yet it may be possible to count fingers at three or six feet distance. By the ophthalmoscope one may even see the optic nerve. The special feature is that there is evidently a most irregular type of refraction in the lens; the same kind which is familiar in conical cornea, or with diffused opacity of the cornea. The retinal vessels, if seen by the upright image, are twisted and undergo great distortions upon parallactic movements. Viewed from the distance of a foot, and by moderate illumination, the irregular shadows flitting across the pupil, and the twisted cycloidal and spiral movements of the vessels clearly point out the irregular refractive quality of the lens and explain the impaired sight. Such eyes may have become myopic in the strict sense. There may be narrow striæ running down from the margin of the lens, but there will be little disorganization of the superficial layers. These lenses pass through their changes very slowly, and many times is an error made in prognosis as to the period when sight will be wholly lost.

I merely allude here to the myopia of senile cataract, which depends chiefly on increase in the refracting index of the lens. When a certain degree is attained, it may for a long time stand with little change, or may end in cortical opacification and complete blindness. I have seen such myopia amounting to 3 and even 5 dioptrics; lower degrees of 1 D and 2 D are common. These are the cases of so-called "second sight."

The practical point respecting the cataracts now referred to is that they should not be refused an operation on the ground of their immaturity. I can from personal experience cite many instances to justify this dictum.

M. J. S——, aged forty-eight, Middletown, N. Y. O. D. lens deep red, posterior polar opacity, and numerous molecules and no striæ; V= fingers at one foot. In O. S. appearances less intense, but similar; counts fingers at five feet.

J. P——, aged eighty-five. O. D. lens perfectly black, no reflex from fundus. O. S. has three fine striæ on nasal side, diffuse haziness of lens, a silvery lustre of surface coming from the capsule; V= 5 $\frac{8}{10}$.

C. F. Y——, aged fifty-one. O. D. lens semitransparent, fine striæ, molecular haziness, no cortical opacity; V= fingers at five feet. Seven months later, appearance of lens and vision the same. Extraction followed by vision =1, or $\frac{20}{20}$. In O. S. same appearance; operated on seven months after, and in that ultimately V= $\frac{20}{20}$.

It is needless to cite many cases; nor have pains been taken to indicate them in the statistics, because they are usually set down as unfit for operation. But in my experience this opinion is unsound, because a perfect separation of the lens from its capsule is possible, and the pupil is easily rendered clear at the operation.

Wholly different is the aspect of a truly immature cataract whose cortical layers have begun to disintegrate with the shrinking of the nucleus. Broad striæ, a deeper opacity, with intervening clear spaces, denote important differences. To this class the operation of massage of the lens, with iridectomy (Förster), and sometimes without iridectomy (Pooley), is in general acceptance. This was done in 34 out of the 309 cases, or in about ten per cent. It is employed when useful vision has ceased, to avoid a long delay in the natural maturity of the lens.

To some cases this proceeding is inapplicable, and it is important to signalize them. First are the sclerosed

lenses above referred to; 2d, posterior polar cataract which usually accompanies choroidal disease; 3d, cataract in myopia; 4th, laminated cataract (congenital). In general it is not suited to cases where the lens is disposed to induration and where the cortical layers have not already shown signs of disintegration. The practice of some is to needle the lens to hasten maturity, but this involves risk more serious than does massage. The effect of Förster's operation on the subsequent operation and during the healing will be hereafter referred to.

It is important to remember that the lens in very old persons is always large, and grows larger with age. We owe this fact to the studies of Mr. Priestley Smith, and of course sclerosed lenses are large. There may be a small cornea, or by a broad arcus senilis it may seem small in diameter, while the lens will be 8 mm. in diameter. It is unnecessary to refer to hypermature cataracts, except that it is difficult sometimes to extract the nucleus because it is small, and also that hypermature cataracts will permit removal in the capsule not infrequently, because the anterior part of the vitreous is also likely to be fluid the capsule will separate from it, and the suspensory ligament will be weak and easily rupture.

2d. The operation chiefly practised is one called by Graefe's name, but which really is a peripheral section at the upper margin of the cornea, with iridectomy, which by some is made broad and by others is made narrow; my own preference is for the latter. Since 1884 cocaine has become the approved anæsthetic, while ether and chloroform are reserved for timorous and unruly patients, or for cases of special difficulty. It will be found that a large proportion of the failures and of the defective medium results, are among those who take ether. While cocaine has vindicated the high expectation in eye surgery with which it was greeted, it has certain disadvantages. It desiccates the cornea and makes the epithelium easily rubbed off. Used in very strong—say ten per cent. solution—it is capable of making it deeply hazy. It need not be used in more than two per cent., or at most four per cent. solution once, or at most twice, with an interval of fifteen minutes before the operation. A second disadvantage is, that it causes diminution of tension. This is seldom carried so far as to be troublesome, yet it has been to me the cause a few times of difficulty in making the section, because of deficient resistance. I have even seen the cornea dimple under the point of a sharp knife. In cases of plus tension its effects are difficult to be procured.

The practice of washing the eye with antiseptic fluids has become habitual. The usual fluids have been boric acid, four per cent. corrosive sublimate, 1 : 5,000, and biniodide of mercury (Panas' solution), 1 : 20,000. None of these are truly antiseptic, yet they aid in removing mucoid secretion from the conjunctiva, and are of special value for ridding the eye of blood and getting out cortical matter. A bulb of one ounce and a half capacity, with a hard-rubber nozzle one and a half inch long, is satisfactory. It is to be stated that solution of corrosive sublimate will, if the corneal epithelium be desiccated by cocaine, cause an opacity which may be serious. The choice between one form of fluid or another is not easy to decide. The majority of cases have been irrigated with corrosive sublimate, yet results equally good have followed boric acid, so far as could be determined. It seems true that, while cleansing of the skin of the lids and of the tarsal edges and of the conjunctival sac by a simple aseptic fluid has advantages, these proceedings give no absolute guarantee against suppuration. Instruments are carefully rendered innocuous by immersion in carbolic acid five per cent., and then dipped in alcohol; the hands of all concerned are scrubbed with soap, and the nails cleansed by a brush, assisted by free use of powdered borax.

An important feature of operations is the use of the bulb to wash out of the wound and of the anterior chamber, blood and the débris of the cataract, besides helping to force the iris back to position. It is not needful to put the point of a syringe inside the eye, the stream is large enough and forcible enough to find its way within. The fluid should be lukewarm, and all those above mentioned seem to answer well without irritating the iris. The mercurial salts have the advantage of coagulating the cortex and making it more visible. The use of eserine, either on the dressing, mixed with vaseline, or in solution in the eye, has been frequent, and seems to be useful. On the other hand, some operators have used atropine in strong solution, gr. xvi. ad oz. j. The choice of agents depends, it seems to me, on the presence of retained cortex, which indicates a mydriatic; while a normal operation, a disposition to prolapse of iris, or the loss of vitreous indicates eserine. The latter is certainly demanded when no iridectomy has been done. The method of opening the capsule has been various; sometimes peripheral, usually central, and with the design of making a thorough laceration. The prevention of its entanglement in the wound is highly important, and is favored by irrigation with the bulb.

The size of the corneal wound is a prime factor in the proceeding. For myself, after some disagreeable experiences, this error no longer happens. I have no hesitation in making it two-fifths of the corneal circumference, although this measure is seldom fully reached. It is extremely difficult to measure exactly the size of the wound. If one follow diagrams, the wound is almost certain to be too small. The depth of the anterior chamber and the diameter of the cornea cause serious differences, because a single millimetre is greatly important. What results from a scanty wound may be noted in the disposition to loss of vitreous, with consequent necessity, in some instances, of introducing delivering instruments, or in the resort to a hook or spoon, even without loss of vitreous. Better is it to enlarge a wound with scissors, than to attempt to force a lens through an opening too small. Iridocyclitis, even suppuration, wait on such mistakes.

Hemorrhage is always annoying, and may be extremely troublesome. It not only may make the operation difficult, but often involves bruising the eye to secure a clear pupil. It comes from wounding the conjunctiva, or from the limbus, and especially from the iris. It is favored by a state of reduced tension, but it especially indicates degeneration of vessels. Under ether we are especially liable to be annoyed by it. I have noted that it often precedes severe iritis and favors thickening of the capsule. Irrigation, actively kept up, is the best means of removing it. It is far better than massage. In case the counter-puncture falls behind the limbus we are liable to hemorrhage, and we always incur another difficulty in the irregular contour which the wound is pretty sure to have, and to it can be attributed some cases of iridocyclitis. In a number of cases the iris has fallen over the knife before completion of the wound. This accident happens more frequently to certain operators. It is, in some measure, due to the resistance of the patient, and to the subtension of the globe. Its effect is not by any means so detrimental as is that of an inadequate wound, yet it implies violence, and is to be deprecated.

Escape of vitreous is the danger most earnestly striven against. It happens at any stage of the proceeding, but is most frequent when the lens is being expelled. If the operator have luxated the lens in using the cystitome, he must be wary of it. Either his hand has been too heavy or the vitreous is fluid in its anterior portion. Loss of vitreous before the lens is out is most untimely, and necessitates the introduction of an instrument for delivery. It is often the patient who is to be blamed for the accident, especially after delivery of the lens, and its prevention will test the tact, temper and patience of the operator like nothing else in surgery.

The importance of the occurrence is shown in the following figures: Among 21 failures, loss of vitreous happened 9 times; among 31 cases giving only moderate visual results, in which surgical faults were committed, loss of vitreous occurred 7 times. That is, in 52 imperfect cases 16 times did this accident happen. On the

other hand, this accident took place among 245 successful cases 33 times. In other words, the chance of escaping ill-effects was about 2 to 1, and the mishap occurred in about 16 per cent. of all the operations. The question whether it happens more or less frequently under general anæsthesia has not been examined. Not infrequently the lens emerges with the vitreous, in other cases it sinks out of sight. Prognosis is better if the vitreous is fluid, than if it be normal in structure.

Entanglement of the iris or of the torn capsule in the wound is a recognized and serious error. It can be avoided by irrigation and by passing the spatula gently along the angles of the wound. In case the tension of the globe is supranormal, even after the lens is out, there is decided liability to iris prolapse. We by no means guarantee exemption from this mishap by iridectomy. On the contrary, very numerous cases attest the occurrence of incarceration of the pillars of the coloboma, and cystoid cicatrices testify to its existence. To the operator this may remain unknown for many days, and it happens both early and late in the healing process as well as at the time of operating.

Out of 309 cases which form our present material, iridectomy was done 274 times. In 35 cases no iridectomy was done, and this is sometimes called simple extraction. These operations were nearly all done by two operators. Although the number is very small, it is proper to give the peculiarities and results of the method.

The incision must always be of full proportions. I have made it at least two-fifths the circumference of the cornea, and it should lie in the limbus, not at all in the sclera. It is placed more peripherally than the old flap extraction, and practically in the same region which is usually chosen in the so-called Graefe's method as now done. Division of the capsule is necessarily central, because the pupil is never dilated intentionally. Expulsion is more difficult than with iridectomy, and requires pressure and counter-pressure, and the lens must make a nearly quarter revolution to enter the pupil and reach the wound. If the pupil be rigid, the attempt must be given up. Replacement of the iris may spontaneously occur, or be induced by irrigation, or effected by the spatula. The real difficulty lies in clearing the pupil of débris. Massage accomplishes much, but irrigation is decidedly the most effective, while introduction of curettes and spoons is to be deprecated. Cases with much soft cortex are undesirable, while the full, hard cataracts best lend themselves to this method. Most troublesome are the very small cataracts, say 5 mm. in diameter, which fortunately are rare. We meet them as nuclei of hypermature cataracts, and very seldom without this degeneration. After completing the operation eserine is to be used freely both by instillation, gr. ss. ad oz. j., and upon the pad, gr. j. ad. 3 j. vaseline. In the 35 cases vitreous was lost five times; in one instance with simultaneous expulsion of the lens. The accidents to the iris were prolapse in 6, and drawing up of the iris toward the wound in 5. The latter is a partial entanglement confined to the peripheral part, and in some instances may be due simply to exudation extending from the wound to the iris. In one case the iris was drawn up apparently behind the wound, as if it had adhered to the ciliary processes—a condition similar to what is sometimes seen after a blow. The lens was in this case extremely small and difficult of delivery; there occurred loss of vitreous and yet vision was $\frac{2}{10}$. The period when prolapse of iris was noted varied from the third to the seventh day. The eye was, in most cases, not opened until the third day, or even later, and it is impossible to say when the hernia occurred. Supranormal tension, which we sometimes find, favors prolapse, but it is clear to my mind that the primary factor is tardy union of the wound. If it had been contused by difficult delivery, by frequent introduction of instruments, if hemorrhage has been abundant, if vitreous has escaped, these circumstances hinder the quick and firm coaptation and healing. Research in cases of death soon after normal extraction of cataract shows that the epithelium dips down into the wound and constitutes a large element in the callus, as it may be called. Lymphoid cells are seen gathering in great numbers from the corneal substance; but epithelium has far more to do in the new tissue than has been supposed. See my case published in "Transactions of the American Ophthalmological Society," 1887, and Becker's cases, especially Taf. xxx., Fig. 2, "Atlas der Patholog. Topographie des Augues," 1874, where the early healing of the wound is shown to occur principally from the outside. Now the pressure of any foreign matter, like clot or lens substance, keeps the wound apart on its inside lip, and restlessness of the eyeball will tend to favor yielding of the cut. Add to this swelling of the corneal tissue adjacent to the wound, and the preparatory arrangements are fully realized, for entrance of the iris. This in my case of death with autopsy of the eye occurred in spite of a normal operation and normal healing process; and being a Graefe's operation with iridectomy, it might not have been noted but for the early death and examination. As a fact, intrusion and entrapping of the iris in the wound has been a frequent occurrence in extraction with iridectomy, taking place at the pillars of the coloboma, and causing many serious complications. It is my conviction that the relative proportion of prolapse of iris in extraction with iridectomy, and without iridectomy, would be found only slightly larger in the latter case if the operations in both were done with especial smoothness and exactness. It is, however, true that for simple extraction the wound must be ample, exact, correctly placed, and regular, and there must be the minimum of exposure and manipulation of the eye. All these conditions imply highly developed technical skill in the operator, and docility in the patient.

It will be noted that there were no failures in the 35 simple extractions; and as to visual results successful cases were 27; medium, 7; unknown, 1. The visual acuity does not exceed the average of the cases with iridectomy, and this result accords with the observations of others.

The incidents of the cases where the lens had been ripened by doing Förster's operation, *i.e.*, iridectomy, with concurrent massage of the lens, deserve to be considered. There were 34; of which successes, 24; medium vision, 7; failure, 3. Extraction is reduced to extreme simplicity; yet that the dangers in the operation are considerable appears from the frequency of loss of vitreous, viz., 10 times, and in four instances instruments were needed for delivery. The date of the first operation varied between one week and eight months. In all cases considerable cortex is encountered, and vitreous prolapse is frequently met with in getting this out. Often the patient, who on a previous occasion has behaved well, now loses self-control. In 8 cases iritis occurred, and in 4 of them it was slight. Certainly the tendency to iritis is important. Failures occurred 3 times, once by iridocyclitis after spontaneous extrusion of lens and vitreous; in another case by secondary hemorrhage after loss of vitreous (the eye was myopic); in the third case no account is given of the reason for failure.

3d. The incidents of the healing process. In the cases of failure, which were 21, they may be grouped into: infection of the wound, 9 times; severe iritis and iridocyclitis, 10 times; vitreous in wound, 1; hemorrhage, 1. One patient is said to be corpulent, which is unfavorable; one is marasmic; another a drunkard; one eye had pterygium; another had chronic conjunctivitis. As already said, in 7 cases loss of vitreous attended the operation. The actual cautery is of no avail when infiltration has passed much beyond the wound, and drawing out the exudation cannot always be effected.

4th. In cases with medium results, which were 43 in all, the defective vision was due in 14 to faults in the eye existing prior to the operation, such as maculæ corneæ, 5; atrophy of choroid, 5; atrophy of optic nerve, 2; detachment of the retina, 1; pterygium, 1; = 14. The cases

surgically faulty exhibited infiltration of the cornea, 8; hypopyon, 1; iritis, 8; slow union of the wound, 1; thickening of the capsule, 10.

Among the 245 successful cases, 117 had to contend with irregularities in the operation, viz., loss of vitreous, 33; severe hemorrhage, 35; unintentional cutting the iris during section, 20; scanty wound, 13; the use of instruments to deliver the lens, 14; injury of the eye during the healing, 2.

Infiltration of the wound happened in 3; hypopyon, 2; severe iritis, 9; opacity of cornea, 5; reopening of the wound, 5. For purulent infection of the cornea the galvano-cautery was used, and in one case three times. Opacity of the cornea was due in some degree to the usual traumatic keratitis, but it was likewise produced by the corrosive sublimate even when only 1 : 5,000, and to this result I have no doubt cocaine contributed. Reopening of the wound is due largely to enfeebled condition of the patient, and is to be met by stimulus and feeding and pressure bandage. In all the cases of reaction the regular treatment is prolonged use of hot water, atropine, washing out the eye if secretion exists, leeches, quinine, alcoholic stimulus in those whose feebleness or previous indulgences demand it. In a few instances—not more than four or five—the lids were closed by plasters; in all the others a bandage was employed and not removed until the third, or the fifth, or the seventh day. Confinement to bed was from two to ten days, or perhaps more. Practice in this regard is various. One notable case was a patient of mine who had lost one eye by an unsuccessful operation at the West. A solution of bichloride of mercury, 1 : 2,000, was used to wash the skin about the eyes, and 1 : 5,000 to the conjunctiva. In twelve hours he developed an intense erythema, simulating erysipelas; the bandage was removed, nothing but cold lotions applied, and the healing of the eye was uneventful; he obtained vision $\frac{20}{40}$.

5th. The number of secondary operations has not been calculated; of them the record is imperfect. It is to be mentioned that they are not always innocuous. They sometimes set up severe inflammation, viz., purulent iridophakitis. Why this should occur when a simple needle wound is made, and thorough disinfection practised, is not to be explained by introduction of germs from without. It must occur by exciting to activity germs already existing in a dormant state within the eye. Such surprises ensue in cases where severe reaction followed the original operation. They have occurred to me mostly where the capsule was both thickened and adherent. On the other hand, an iridotomy with Wecker's scissors or a knife, even when we are dealing with tissues deeply damaged by inflammation, is seldom followed by so great mischief. An iridectomy is rarely followed by harm. I have several times lost eyes by secondary needlings, while the more serious secondary operations are borne with much greater impunity.

In summing up the cases which have been utilized, the result of operations upon 309 cases was as follows:

Successes with vision $\frac{1}{10}$ and better	245, or 79 per cent.
" " " less than $\frac{1}{10}$	43, or 14 " "
Failures	21, or 7 " "
	309

If careful selection of cases had been made, the showing would have been much better; but while the surgical repute of the operators would have stood higher, the nobler attributes of the surgeon, who puts all his powers and capacities at the service of the distressed, would have been tarnished. There were eight operators, of whom five contribute 139 cases, with full success, 78 per cent.; partial success, 13 per cent.; failure, 9 per cent. Of three who contributed 172 cases, the results are: full success, 80 per cent.; partial success, 14.7 per cent.; failure, 5.3 per cent. The personal equation appears not so much in the proportion of full successes as in the category of partial successes and of failures. A very large portion of the patients were of the true pauper class, and many the victims of evil habits.

It must be added that two cases of sympathetic ophthalmia occurred among the 309, and two deaths took place, one from heart failure and one from general exhaustion.

The degree of vision in successful cases is shown in the accompanying table. In some instances secondary operations were done, but the proportion was less than one-third. In 21 cases no record of vision is given, but the results were known to be successful.

$\frac{20}{200}$	39 cases.
$\frac{20}{100}$	46 "
$\frac{20}{70}$	61 "
$\frac{20}{50}$	35 "
$\frac{20}{40}$	29 "
$\frac{20}{30}$	7 "
$\frac{20}{25}$	5 "
$\frac{20}{15}$	1 case
$\frac{20}{10}$	1 "

THE DIAGNOSTIC SIGNIFICANCE OF TREMOR.[1]

By GEORGE J. PRESTON, M.D.,

PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE BALTIMORE POLYCLINIC; PROFESSOR OF PHYSIOLOGY IN THE WOMAN'S MEDICAL COLLEGE OF BALTIMORE.

TREMOR may be general or local, that is, it may embrace the whole muscular system, as the mercurial tremor; or it may be confined to certain groups of muscles, as in atrophic affections; or be limited to a single member, as the tongue or lips. The distinction of convulsive and paralytic tremor is a very old one, running back, in fact, to the time of Galen. The former, which persists during repose, was supposed by Van Swieten to be due to an irritative lesion, while the latter, which is seen only on the occasion of voluntary movement, was attributed to a deficit of the normal stimulus. The older theory of Spring and others, that tremor was due to some alteration in the tissue and contractility of muscle, has been displaced and disproved by the experiments made some years ago by Charcot and Vulpian, which showed conclusively that, in most cases at least, tremor is due to central nervous influence. As Romberg puts it, tremor is the bridge which unites spasmodic and paralytic affections.

As we know, muscular contraction is brought about, not by a single stimulus, but by repeated, successive stimuli, the summation of these giving what is known as physiological tetanus. Now, to produce this condition it is necessary that these stimuli exceed thirty-two per second. When a normal muscle contracts these rapid stimuli run together, as it were, and give a steady movement, and the individual stimuli cannot be appreciated except by applying the stethoscope to a contracted muscle, when the humming bruit can be distinctly recognized. This principle is, of course, the well-known one of the rapid vibration, as of the waves of light or sound, giving a continuous picture or note. When a wheel is revolving rapidly we cannot discern the individual spokes, but as soon as the velocity falls below a certain number of revolutions they become visible; so, when the stimuli to a muscle fall below thirty-two, we begin to recognize each individual stimulus in its resulting contraction. Now, in such diseases as paralysis agitans, multiple sclerosis, mercurial tremor, and the like, the number of contractions—for, of course, tremor is nothing more than successive contractions and relaxations—has been shown by Brouardel, Marey, Gowers, and others, to reach only six or seven per second. So that in certain affections, where the conducting motor-tracts are affected, as, for example, in disseminated sclerosis, it becomes evident that the cortical motor discharge is not properly conducted—is interrupted in precisely the same way as an electric current might be. This same thing is well shown in the fibrillary con-

[1] Read before the Clinical Society of Maryland, March 1, 1889.

tractions of many atrophic diseases, where certain parts of the same muscle, or one muscle in a group, will not receive its proper stimulus, and instead of the steady tonic condition, it is alternately contracting and relaxing. We should bear in mind, in considering the subject of tremor, the fact of muscle tonus. In certain affections there is seen a want of co-ordination, a destruction of equilibrium between antagonistic muscles, and as a result a tremor. While, as has been said, we may make a distinction between the convulsive and the paralytic tremor, as shown by the application of some stimulus such as an electric current, which exaggerates the former and diminishes the latter; still, in the great majority of cases, tremor is of paralytic origin. Before taking up the individual tremors, the following classification, which has been somewhat modified from that given in the excellent treatise of Axenfeld and Huchard, may make the subject clearer.

Tremors may be divided into the *acute*, embracing those produced by *a*, cold; *b*, fright, anger, or great emotion; *c*, adynamic fevers.

It will not be necessary to describe any of these acute forms, but they should be borne in mind in making a diagnosis. Nervous females, especially when being examined by a physician, show often in a marked degree this acute tremor. The *chronic* form includes: *a*, Cerebral or spinal lesions, such as primary lateral sclerosis, disseminated sclerosis, ataxic lateral sclerosis, post-hemiplegic affections, bulbar paralysis, general paralysis, myelitis, by compression especially, and certain forms of chronic meningitis; *b*, lesions of nerves and muscles, as neuritis and muscular atrophies; *c*, metallic poisons, as mercury, lead, arsenic, along with which may be classed the tremor of syphilis, alcohol, tea and coffee, and tobacco; *d*, certain affections, the pathology of which is not understood, paralysis agitans, hysteria, exophthalmic goitre, athetosis, senile and hereditary tremors, and a certain form described as simple tremor, and chorea. Of course a great number of these forms need not be discussed, and are mentioned only to make the list complete.

1. *Disseminated sclerosis.*—Of cerebro-spinal lesions, disseminated sclerosis, sclérose en plaques of the French writers, presents most prominently tremor as a marked and constant symptom. The first thing noticed in regard to the tremor of this affection is that it exists only upon some voluntary movement. If the patient be lying in bed no tremor whatever is observed. When sitting in a chair, tremor of the legs may be seen. Certain movements involving only very limited play of the muscles, as for example in buttoning the clothes, may be performed, and the attending tremor is not very marked—is fine. When, however, the movement requires more extensive exercise of the muscles, through a larger arc, then the tremor becomes very decided and characteristic. If the patient be required to raise a glass quite filled with water from the table to the lips, at first the tremor is rather slight, but as the effort is continued it becomes more and more intense. It is rhythmical in nature, the glass being moved toward the mouth and withdrawn in a regularly intermittent manner. The direction is not lost as in chorea, but the glass approaches nearer and nearer the lips, until finally it is struck violently against the teeth and the water spilled. When a patient in whom this disease is pronounced attempts to walk, the limbs, trunk, and head all partake of this tremor. It is true that certain cases have been observed in which the tremor persisted to some degree when the patient was at rest, but such cases are very rare, and can easily be explained by the very wide distribution of the pathological process in this disease. The tremor of disseminated sclerosis is usually an early symptom, though it occasionally appears after the disease has become established. Toward the termination of the malady the tremor often disappears almost entirely. The scanning speech will be noted farther on.

2. *General Paralysis.*—Here the tremor is confined in the early stages of the disease to the muscles of the face and the tongue. The tremor is not general, but limited to certain muscles or even to parts of a muscle, giving the well-known fibrillary tremor. This is well seen in the tongue, which has in addition a general tremulousness of its entire structure, so that its movements are very uncertain and inco-ordinate. In the latter stages of the disease there is a tremulousness attendant upon any movement, which is seen in the whole member moved, together with the rapid fibrillary twitching of portions of muscle. On the whole, the tremor of general paralysis is not specially characteristic, except so far as it affects the muscles of articulation. The difference between the tremulous, indistinct, uncertain utterances of a general paretic contrasts sharply with the regular, spaced, scanning speech of a patient with disseminated sclerosis. Of the other brain and cord lesions which may give rise to tremor, it is not necessary to speak specially. In none of them does the tremor exist as a characteristic and diagnostic symptom. The remarks apply to the various forms of neuritis and muscular atrophies, in which latter fibrillary tremor is well marked.

Turning now to certain affections the pathology of which is either unknown or inconstant, the one in which tremor is most characteristic is

3. *Paralysis agitans, or Parkinson's disease.*—Of all the diseases mentioned in the foregoing table this one presents the most marked, persistent, and diagnostic tremor. The tremor in this affection is fine, that is, the arc of movement is a short one. At first it is confined to one member, but as the disease advances it becomes more general. The movements are regular and more or less rapid, the favorite seat being the hand. Here the movement of the thumb against the other fingers has been compared to that observed in rolling a pencil between these fingers, or rolling pills. The handwriting, which in disseminated sclerosis is irregular and angular, and in general paralysis is distorted and full of omissions, in paralysis agitans is characterized by the lines being finely sinuous. In the earlier stages of the disease this is appreciable only by means of a lens. A distinguishing feature of the tremor in this affection is that it exists only during a state of repose. If a patient whose hand is continually agitated attempts to grasp some object, the tremor in large part disappears, or at least is not increased. While, as has been said, the tremor usually begins in one member, it may affect all four, or may take a hemiplegic form. A fact to be noted is that it spares the head.

4. *Senile tremor.*—Very closely connected with the last mentioned affection is the tremor often seen in advanced age. Its favorite seat, differing greatly in this respect from paralysis agitans, is the head and neck, giving rise to the frequently observed nodding motion. At first this tremor seems to be lessened when the parts affected are at rest, but later in the disease it becomes continuous and widespread. It is solely a disease of very advanced age, excepting of course certain cases which occur in persons who have all the evidences of extreme old age except the years. It varies in degree from that slight tremor and want of co-ordination which always accompanies a burden of years, to a more marked and continuous rhythmical tremor, resembling paralysis agitans in almost every respect save that in that disease the head is free.

5. *Exophthalmic goitre*, or Basedow's disease, presents a very characteristic tremor, which was noted only a few years ago and has since been carefully studied by Marie. It is a fine tremor, a vibration, which affects not one member, but the whole body. If the patient is erect, by placing the hands on the shoulders or the head this vibration is quite perceptible. The tremor varies considerably in different cases, but is nearly always present if carefully looked for, and is often a very prominent feature.

6. *Choreiform movements.*—In ordinary chorea vulgaris there is no defined tremor. The movements are extremely irregular, persisting during rest, and very greatly exaggerated in voluntary movement. In striking contrast with disseminated sclerosis, the choreic patient in attempt-

ing to put a glass of water to the lips makes a number of wild, irregular movements, without the slow advance to the end aimed at in the other disease. In many cases, however, chorea assumes a rhythmic form, and then is apt to be confounded with other forms of tremor. Still, close attention to the irregularities of the intentional movements, as well as the fact that the tremor, or more exactly the spasmodic movement, exists during rest, will lead to a correct diagnosis. Some of the uncommon forms of chorea, such as the hereditary form described by Huntingdon, and the various pre- and post-hemiplegic forms, present a more distinct trembling. To the same category belongs athetosis, where the constant polyp-like movements are limited to the fingers and toes.

7. *Hysterical tremor.*—The movements observed in hysteria are as various and simulating as the other symptoms of this disease. The tremor may be limited to one side, hemiplegic in form, or may be general. It may consist of a fine tremor, continuous but much increased by movements, or it may show a violent convulsive discharge. A characteristic feature of the tremor is its irregularity. For a time the movements may go on with almost the regular rhythm of paralysis agitans, when suddenly they will be replaced by violent convulsive movements. There is at present under my care a young woman who presents a most marked hysterical tremor. All four limbs are agitated by a tremor of rather wide range, coarser than that of paralysis agitans, and rather more rapid. Any excitement, or any movement will intensify greatly the tremor. If she attempts to put her feet to the ground at once the regular movement is transformed into a very violent convulsive form, almost resembling spinal epilepsy. Choreiform movements are often met with in hysteria, and should not be confounded with that disease.

8. There is a curious and rare form of tremor which, for want of a better name, or because it is the sole symptom, is known as *simple tremor*. It affects young or middle-aged persons and is generally confined to the hands, lips, or tongue. Usually it ceases during rest and is aggravated during movement, though to a considerable extent under control of the will. It is a fine tremor, and rather rapid. A number of cases of this simple or nervous tremor have been described, showing a marked hereditary tendency. It has no special ill effects on the health of the person affected, but is very resistant to any form of treatment, and often continues during life.

9. One of the prominent symptoms of chronic poisoning by certain metals is tremor. Of the metals occasioning such tremor, the most notable is mercury. Poisoning by this substance is met with occasionally after long-continued therapeutic administration, either taken internally, by inunction, and especially by the vapor bath, but most frequently among artisans who use the metal or who prepare it for commerce. The tremor usually commences in the face or arms, and gradually invades the trunk and lower extremities. At first it is present only on voluntary movement, but soon persists during repose, and in extreme cases even during sleep. It resembles the tremor of disseminated sclerosis, though less extended. Generally, the character of the tremor would be represented by a mean between disseminated sclerosis and paralysis agitans. As the disease advances the tremor becomes more violent and convulsive. In chronic lead poisoning tremor is an inconstant symptom, generally limited to the face or hands. It is a fine tremor, resembling senile tremor, and is worse after exertion, when the muscles are exhausted. Slight tremors are sometimes observed in cases of chronic poisoning by other metals, but they are not worthy of special mention.

10. *Alcoholic tremor* is met with, as has been said, in acute alcoholism. In this case it presents the form of a moderately fine tremor, most marked in the face and hands, but seen also in the lower extremities. It is exaggerated on movement, becoming faint or entirely disappearing if the patient can be quiet. A distinctive feature of the tremor of acute alcoholism is its tendency to become general, so that when the hand is placed on any part of the patient, a trembling can be felt which runs through the whole body. Very often, in fact almost always, this tremor increases in intensity until it becomes convulsive. The tremor of chronic alcoholism is in many respects similar to the slighter acute forms. It attacks almost exclusively the face, especially the lips and tongue, and the hands. It is a fine tremor, and with it is associated fibrillary contractions of the muscles, so that the picture presented is very like that of general paralysis. Fournier has described a syphilitic tremor, appearing with the secondary symptoms of that disease, but it can hardly be called distinctive.

The foregoing forms of tremor have been selected and dwelt upon because they are characteristic, and in many instances diagnostic. It should be borne in mind, as noted above, that tremor may occur in many other affections as a complicating or transitory symptom. Notably is this the case in brain and cord lesions. Whenever the motor tract is invaded, then we may have tremor. Also in all the many forms of hysteria, tremor is a very frequent symptom.

General diagnosis.—When a case presents itself in which tremor is a constant symptom, the first thing to be noted is its extent, whether it is general or local; whether it affects a whole limb, a group of muscles, one muscle, or simply certain fibres of muscle. Then, as to whether it is continuous or occasioned only by voluntary movement; whether it lessens or increases as the muscles become tired, or if it ceases altogether when perfect rest to the affected part is induced. As to the nature of the movements, it should be noted whether they are regular and rhythmical, or jerky and interrupted, and the number per second should be counted. The patient should be made to extend the arms with the fingers separated, for in this way the finer movements can be seen. Often, when one is not certain about the presence or absence of tremor, if the observer's hand is pressed lightly against the tips of the extended fingers of the patient the vibrations can be felt. One of the simplest and best tests of many forms of tremor is to ask the patient to raise a glass filled to the brim with water, from the table to his lips, or to use a spoon as in eating. If possible tracings should be made, which can be easily done by means of the modified instrument of Marey. The lower extremities should be tested in various ways, and the peculiarities of the gait noted. By careful attention to these details one is often enabled to correctly diagnose certain obscure affections in which tremor is a significant symptom.

9 East Townsend Street.

Antipyrin in Laryngismus Stridulus.—Dr. Montague Perceval, writing in *The Lancet* of November 17, 1888, recommends very highly the use of antipyrin in laryngismus stridulus. He reports the case of a child, eighteen months of age, to whom he gave the drug in doses of two grains every hour for a few hours until the child fell asleep, and then in the same dose every two hours. The following day the little patient was well. The author used the remedy in twenty-three other cases with equally favorable results, except that in one case it was necessary to increase the dose to five grains before the paroxysms ceased.

Iodide of Potassium in Aortic Aneurism.—Dr. Berényi reports in a Hungarian journal a case of aortic aneurism, accompanied by distressing symptoms of dysphagia and nightly attacks of urgent dyspnœa, in which marked relief was afforded by iodide of potassium in doses of half a drachm daily. At the time of the report the dysphagia and asthmatic attacks had disappeared, the hoarseness from which he had suffered had improved, the area of dulness over the aneurism had grown less, and the patient had gained several pounds in weight. Over five ounces of the iodide had been taken without any signs of iodism.

UTERINE ADENO-SARCOMA WITH PYOMETRA.[1]

By THOMAS W. KAY, M.D.,

EX-SURGEON TO JOHONNITER HOSPITAL, BEYROUT, SYRIA.

The coexistence of adeno-sarcoma and pyometra in the same uterus is so rare that I am induced to bring the following case to your notice. Pyometra, of itself, is not common, as may be seen from the small space devoted to it in books on gynecology. Out of some sixteen consulted, I find it mentioned in only two, viz., Billroth and Fritsch.

It usually occurs in old people where atresia of the internal os exists, and is due to a retention of the secretions. In this case it was due to closure of the internal os by the suppurating growth.

Adenomata of the cervix are quite common in the form of small polypi composed of retention-cysts with hypertrophied walls. In this form they also exist in the uterine cavity, where a much rarer form is sometimes found. This has a broad base, and is not composed simply of hypertrophied glands, but contains new glandular formation.

These growths are diffuse, rich in blood-vessels, and, according to Winckel, infiltrated with round sarcomatous cells.[2]

Cases of this kind have been reported by Duncan, Guesserow, Schröder, Thomas, and others.

The growth in the following case probably began as this, and afterward became sarcomatous. May tells us that uterine adenomata are frequently admixed with sarcoma in the form of adeno-sarcoma.[3] Billroth remarks that "pure adenomata (which are rare) may be difficult to distinguish from sarcomata which have developed in glands (adeno sarcomata)"[4]

Thomas reports a case which seems to have been the same kind of growth as in the following. It was examined by Dr. W. H. Welch and pronounced to be a mixture of sarcoma and adenoma.[5]

Case.—Lateefy, a multipara, fifty-two years of age, was sent me by Dr. Yusuf Abu-Suleiman, of Lahley, to enter the Johonniter Hospital, of Beyrout, Syria. She complained of an offensive discharge at times from the vagina, accompanied by colicky pains. The menstrual flow ceased some ten years before, and since that time she had suffered more or less from leucorrhœa. The offensive discharge was of eight months' duration, and the pain had lasted nearly as long. Emaciation was great and cachexia was marked. Bimanual examination showed the uterus much enlarged and extending well up into the abdominal cavity. The external os would admit the end of the little finger with difficulty, and a soft friable mass could be felt in the cervical canal. The uterine probe was introduced with difficulty in front of this mass, and gave a depth of eight inches.

Assisted by Dr. I. Mutter, the woman was put in the left lateral position, a speculum introduced, and the anterior lip seized with vulsellum-forceps and well drawn down.

The cervical canal was now rapidly dilated with steel urethral sounds until the index-finger could be introduced. While this was being done, a constant flow of most offensive pus took place, till some eighteen to twenty ounces had been evacuated.

On introducing the index-finger the growth was found to cover much of the posterior uterine wall, and it was attached nearly down to the internal os. Its base was broad, and its surface irregular, soft, and sloughing. A large part of this was removed by the blunt curette, the uterine cavity washed out with bichloride solution, and the woman put to bed. Antiseptic injections were used daily, and iron and ergot were given internally. All went well, and in eight days I again dilated the uterine cavity, and with a sharp spoon removed all roughened elevations from the posterior wall. There was free hemorrhage, but this was arrested by the application of liq. ferri subsulph. Dr. W. T. Van Dyck kindly examined the growth, microscopically, for me and pronounced it an adeno-sarcoma. In three weeks the discharge had entirely ceased, and the depth of the uterine cavity was reduced to three and one-half inches; so the woman was permitted to go home, with the prognosis of a probable return of the growth.

A CASE OF PLACENTA PRÆVIA CENTRALIS, WITH ITS SUCCESSFUL MANAGEMENT.

By R. R. BALL, M.D.,

ASSISTANT SURGEON U. S. ARMY, FORT LEWIS, COL.

On October 20, 1888, after returning from duty in the field, I was requested to attend a case of expected confinement. Mrs. W. White, aged twenty-two; multipara; a fairly robust, healthy-looking blonde. On the date above stated I visited the patient, and, on questioning her, found she had been suffering with, as she expressed it, a return of her monthlies while pregnant, for several weeks past. This hemorrhage had at first come on suddenly, without apparent cause. Of late the quantity had increased each time, and on the previous night, during sleep, quite a discharge of blood had occurred, thus awakening her. Strongly suspecting the true nature of the case, I reassured her, on general principles, and then made digital examination.

The os was found moderately soft, the cervix slightly elongated and enlarged.

On entering the finger and carrying it up to inner os some resistance was felt—a peculiar, wormy mass seemed to occlude the os internum.

This mass seemed rather firmly adherent to the right side of the uterine wall. After a careful examination and elimination I diagnosed placenta prævia centralis.

The question of hemorrhage being of primary importance—the history of the case showing it had increased in quantity and frequency—rendered the conclusion that operative interference was essential, for the mother's welfare at least. Though not unmindful that most authorities advise a tentative course in such cases—especially if the hemorrhage occur previous to the seventh month—I at once introduced thoroughly a carbolized tampon around the cervix, leaving it *in situ* for twenty-four hours. These were repeated several times. On removing the last one the whole cervix was found softer, the os more patulous, and the hemorrhage had been temporarily controlled. Still dilatation was not sufficient to proceed to delivery, and normal labor-pains had not set in—which I had rather looked for after the tampon.

Barnes' rubber-bag dilator (next to smallest size) was then carried well up, so as to include inner os, and gently expanded with warm water. After three or four hours the next size was likewise introduced. At the end of five hours this was removed, the dilatation being sufficient to admit two fingers easily, and strong pains having come on.

I then carried two fingers well up and detached the placenta around internal os as far as could be reached, at the same time rupturing the membranes.

After detaching the placenta it receded up the side slightly—when the membranes and fœtus pressed downward—thus checking the hemorrhage, which had been quite profuse at the time of the detachment.

Having accomplished this, I was enabled to make out the position—a breech-case (left dorso-anterior). The pains continued very effective till the child had reached the mid-plane, when they ceased wholly—a condition of inertia coming on. The woman being very nervous and excited, as well as much fatigued by the amount of pain

incident to the preliminary treatment, and no rational indication existing to justify further delay, the question was between ergot and the forceps.

Owing to the impossibility of knowing exactly how far the placenta might still be attached, as well as for other reasons, I decided in favor of the forceps.

A few whiffs of "A. C. E." mixture were then given, and the forceps applied to the breech, which was gently brought down to near the vaginal orifice, when they were removed, the labor being completed by manual means.

The placenta was easily delivered in half an hour, and it was followed by quite a profuse gush of blood. This latter was controlled by persistent kneading (Crede's) —the administration of ergot—and, at the same time, clearing away all clots from the os with the finger.

The child, though born alive, survived only three hours. Its age, as near as I could calculate, was about six and a half months.

The patient then made an uninterrupted recovery, and, no doubt, will venture on her perilous journey again in due time.

As complete asepsis was observed as possible in all details, and at no time did her temperature exceed 101° F.

SPONDYLOLISTHESIS OF TRAUMATIC ORIGIN.[1]

By V. P. GIBNEY, M.D.,

NEW YORK.

The patient is a male, aged twenty-nine, married, and a laborer. He came under my observation for the first time, December 18, 1888, presenting the deformity and gait of an advanced case of Potts' disease, *i.e.*, he walked with body bent forward and to the right, and using much care with every step. He seemed to suffer as he walked, and I naturally supposed him a cripple of long standing.

On getting the history, however, I learned that in a collision he had been thrown from the platform of a horse-car, November 7th, had fallen on his back, receiving a severe wrench as he rolled over into the street, had been helped into a drug store in a dazed condition, and had been soon transferred by ambulance to Bellevue Hospital. The records at the hospital, kindly furnished me by Dr. Chauncey Biggs, House-Surgeon, show that on admission the patient was in a state of shock. A perineal wound was found extending a short distance into the rectum; the back and left side were contused, and he had the following fractures: Ninth rib, left side, at a point about corresponding with the anterior axillary line; tenth and eleventh ribs, left side, at points about corresponding with the posterior axillary lines; spinous processes of the eleventh and twelfth dorsal vertebræ, and probably also the spinous processes of the tenth dorsal and the first lumbar vertebræ. There were no symptoms denoting injury to the spinal cord. Motion and sensation in his legs were not affected.

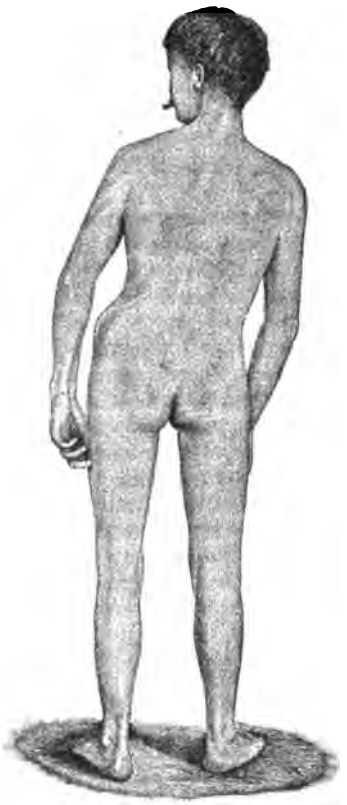
By the following day a large hæmatoma had appeared in the lumbar region on the left side. This was smaller on the next day, November 9th, and soon disappeared. Under stimulants he improved, and was discharged December 14th.

So that I saw him four days later, and the condition I noted was essentially that which presents for your consideration this evening, although on December 20th I endeavored, with patient profoundly anæsthetic from ether, to correct the deformity without avail. I have also, under the impression that a hysterical or a malingering condition existed as complication, employed the Paqueline cautery on several occasions.

The only effect that I can observe as a result of my examination and treatment is an ability to walk with possibly greater facility. He complains of pain in the distribution of the sciatic nerve, right side, and the deformity is unchanged.

[1] Presented to the Practitioners' Society of New York, March 2, 1889.

You see he stands like one prematurely old—body bent forward and to left. The ala of the pelvis on left side is unusually prominent, and apart from the apparent deformity, this would show by reason of the lateral curvature which is shown; this whole side of the pelvis stands out more conspicuously than the right side does. The lateral masses of the sacral vertebræ are more prominent on the right side, and the sacrum in general



gives one the impression that it had been wedged down into the space existing between the alæ of the pelvis. It further seems to be rotated on its vertical axis. The erector spinæ on right side being more prominent than those on left side indicate a degree of rotation of the vertebræ. Motion from the tenth dorsal to the sacrum is not possible. There is no kyphosis, and concussion does not elicit the pain one expects to find in Potts' disease with this test.

In neither iliac fossa can any tumor on deep palpation be found, and there is no reflex spasm excited when the thigh is completely extended.

Limbs appear unequal in length, but careful measurement shows neither real nor practical difference. There is no difference in the size of the limbs, and the functions of the hip-joints are normal. There is apparently much spinal tenderness. The photograph taken a day or two ago, and which I present this evening, does not show the points about the sacrum to which your attention has been called (see photograph.)

In seeking a solution of the difficulty, I am forced to the conclusion that we have in this patient a case of forward subluxation of the last lumbar vertebra on the sacrum, and in addition thereto, a downward displacement of the sacrum itself.

In 1885 Mr. Arbuthnot Lane presented a paper to the Pathological Society of London describing cases of spondylolisthesis occurring in men who carried heavy weights. He was enabled to show from specimens the modification which the lumbo-sacral articulation underwent by reason of the superincumbent weight long transmitted.

My patient seems to have suffered from momentary force rather than long-continued force, and the gross appearances certainly seem explainable on the occurrence of a spondylolisthesis.

Clinical Department.

SOME EXPERIENCES WITH SULFONAL.

By C. M. REXFORD, M.D.,

WATERTOWN, N. Y.

Until quite recently the reports of the results of the use of sulfonal, the new hypnotic, have been decidedly in its favor. Of late, however, some accounts have come from abroad which indicate that it is not so harmless as was at first asserted. This drug seems to be of so much value that exact knowledge of its effects is quite desirable. Its high price has probably prevented a very extensive use of it, and reports of its effects have so far been somewhat meagre.

The writer's experience with sulfonal seems to show that it is about as well adapted to one class of cases as another, and that the only reason for expecting a failure in any given case is the presence of extreme pain.

The first patient upon whom its effects were observed was a woman who, from long-continued nervous strain, fell into a state of complete prostration, attended by intense cerebral congestion, non-inflammatory in character, with violent and constant headache, hallucinations, and finally delirium of a low type, lasting for months. This condition could only be controlled by opiates, and upon their withdrawal, which improvement made possible, it was succeeded by sleeplessness and much pain in the head. At this time sulfonal was put on the market. The first dose gave the patient a night of natural sleep, and the head felt much better the next day. No more perfect result could be desired than the drug produces in this case. A dose of twenty to thirty grains always produces sleep, relieves the distress in the head, and leaves no bad effect whatever. It has only been necessary to use the drug occasionally, and nothing like a habit has been formed.

The medicine was employed in a recent case of pneumonia. The attack was not severe; but the patient, a feeble woman, past middle life, was an extremely nervous and difficult one. Great depression of the nervous system came on, with persistent sleeplessness, which proved wholly refractory to ordinary sedatives. A dose of ten grains of sulfonal was given. No effect, besides greater restlessness, was produced for four hours. Then profound sleep ensued, which persisted for twenty-four hours. During this time it was difficult to rouse her enough to take nourishment. No other ill result followed, nor did the insomnia return. The depth of the stupor produced by the small dose employed was such as to make the result of a larger dose seem rather doubtful. This patient has a weak heart, sometimes intermitting, but it seemed not to be affected by the drug.

Another case was one suffering from chronic metritis. This patient, when first seen, was extremely debilitated by absence of appetite and want of sleep. Fifteen grains of sulfonal at bedtime acted very favorably for a time, but finally failed to induce sleep, and only caused great restlessness instead. Finally, a second dose of fifteen grains was given, four hours after the first. The patient then fell asleep. In the morning she was unable to rise. She complained of giddiness, of being unable to hold the head up, and could not stand or walk without assistance. There was vomiting, and the stomach refused to retain food for many hours. When permitted she slept a troubled, uneasy sleep for the whole day. It was not till the end of three days that she felt herself again. This patient also has a very weak heart, though there is no organic lesion. She is frequently faint, or is obliged to lie down because the heart acts badly. While under the influence of the medicine, as related, the heart-symptoms seemed to be made somewhat worse, but not notably so.

In the considerable number of other cases in which this remedy has been employed it has acted, in the main, favorably. These have been cases of nervous insomnia, and they have all yielded without any difficulty and with no untoward result.

The experience of the writer seems to indicate that sulfonal is a valuable medicine, but that it has its limitations. It is easy to take, it does not often irritate the stomach or produce ill effects. But it may fail to act as expected, and in some instances it may produce extremely disagreeable results. The dose which was at first recommended, of thirty to sixty grains, is too large to commence with. It is unsafe to give more than ten grains as an initial dose, and fifteen grains will prove a sufficient dose in the majority of cases.

INTUBATION TWICE SUCCESSFULLY PERFORMED IN SAME PATIENT.[1]

By JOSEPH EICHBERG, M.D.,

CINCINNATI, O.

The literature of the subject of intubation, which is rapidly attaining that position which the importance and success of this substitute for tracheotomy so justly merit, has furnished us with a chapter of most interesting data of accidents, difficulties, and singular coincidences, but no one has as yet reported, so far as I know, a recurrence of croup in the same subject with a successful issue to both attempts at relief by the intubation-tube. It is, perhaps, hardly to be wondered at, that the text-books make but scant mention of the tendency to recurrence of membranous croup, seeing that, in the past, the first attack usually precluded any possibility of later attacks of this or any other affection by quickly terminating the life of the little sufferer. Even where tracheotomy has been performed with full success I find no history of a second attack of the original trouble, so that it is a most unusual history which I have the pleasure of presenting to you this evening. The patient, a little girl now four years of age, was seen by me for the first time in December, 1887, in consultation with Dr. C. G. Comegys, of this city. She was then in an advanced stage of asphyxia, cyanosis of the skin and mucous membranes being well marked, and the dyspnœa painful to witness. She had been perfectly well until a few days before, when she developed a slight hoarseness, and some cough. The difficulty of breathing had supervened only twelve hours before, and was rapidly increasing. The cough, which had previously been resonant and barking, now had a whistling, stridulous character. There was the usual inspiratory difficulty with depression of the lower portion of the chest-wall, especially marked during inspiration. The tube was promptly introduced and, barring a slight disturbance on the second day, no trouble was occasioned by its presence; and it was finally withdrawn after having been *in situ* just eight days. This is a little longer time than that which is usually held to be within the limits of safety, but the general condition of the child was rather discouraging, and, as she paid no attention to the presence of the tube, it was decided to extend the time slightly. Accordingly, it was not until after the lapse of fully eight days that the tube was removed. The subsequent course of the case was very satisfactory, and, aside from a slight hoarseness and partial aphonia, which persisted for some time, the child's health remained good until November 26, 1888, when I was again summoned to see it. It had, according to the account of Dr. Comegys, complained of some sore throat for almost a week; but there had been no exudation in the fauces, and no hoarseness was noticed until November 22d, when the cough became distinctly croupy and a slight embarrassment of respiration supervened. Emetics, administered for the relief of a supposed slight catarrhal swelling, failed to ameliorate the distress. The difficulty slowly but perceptibly increased, despite all medication, and, at the time of my visit, the anxious face and cyano-

[1] A paper read before the Cincinnati Medical Society, January 15, 1889.

sis of the surface indicated the urgency of the symptoms. The tube was at once inserted, some membrane being immediately expelled; and the child made a perfect recovery. I am sure there was no doubt in the mind of the attending physician as to the presence of an exudation in both attacks, nor is there any such doubt in mine; indeed, on both occasions portions of the membrane were expelled as soon as the tube had passed below the obstruction. As before stated, the entire interest of the case centres in the recurrence of the trouble after the lapse of a year and in the satisfactory result of both intubations.

Progress of Medical Science.

THE OPERATIVE TREATMENT OF PRIAPISM.—Dr. Vorster, surgeon to the Bethany Deaconesses' House, Berlin, has published two cases of priapism, which were successfully treated by Professor Rose by means of operation (*The Lancet.*) The first patient was of a hemorrhagic diathesis, and was admitted to hospital suffering from violent epistaxis. This was soon stopped, but severe symptoms of acute cerebral anæmia remained—headache, vomiting, and extreme feebleness of right arm and leg. Priapism came on in consequence of straining at stool, and further cerebral symptoms followed—insomnia, pains in neck, paralysis of sixth cerebral nerve, and loss of consciousness. The author consequently supposed that the priapism was due to hemorrhage in the brain produced by violent straining. The measures employed consisted of local cold applications, camphor, morphia, and chloral internally, long-continued tepid baths, and even the administration of chloroform, but all proved useless. After the priapism had continued for thirty-two days, Professor Rose determined, notwithstanding the hemorrhagic diathesis, to make an incision in order to relieve the paraphimosis which existed. This was followed by hemorrhage, which continued for three hours. The priapism then began to diminish, and in four days after the operation the penis had returned to its ordinary condition. Subsequently marked splenic leukæmia developed. The author considers, notwithstanding the coincidence of leukæmia with priapism which has been noted in medical literature, that here the leukæmia cannot have been in any way the cause of the priapism, because it was not developed until the latter had ceased. In the second case the priapism was due to hemorrhage into the right corpus cavernosum, caused by an accident. This effusion exercised pressure on the veins, and thus caused stagnation of the venous blood in the corpora cavernosa. Professor Rose, having diagnosed with certainty the occurrence of a rupture of the urethra, proceeded to perform external urethrotomy, with the object of relieving the great distention of the bladder. During the operation a hæmatoma was found bulging forward into the urethra. Upon an incision being made into this tumor the priapism disappeared. The patient was discharged cured in seven weeks.

A RARE CAUSE OF DILATATION OF THE STOMACH.—Dr. Pertik, of Buda-Pesth, has described a singular abnormality, causing obstruction to the onward passage of the contents of the stomach, and leading thereby to great dilatation of the viscus. The defect consisted in a curious pouch of mucous membrane, shaped like the finger of a glove, about eight centimetres in length and three centimetres wide, which projected into the duodenum, with the upper part of which the posterior wall of the pouch was continuous. The first part of the duodenum was much dilated, and its mucous membrane quite smooth, passing continuously into the mucous membrane which formed the internal as well as the external coat of the abnormal pouch. The mouth of the pouch thus looked upward, and anteriorly it had a free lip or margin, close to which the common bile-duct opened, suggesting the possibility of the formation of the pouch in an abnormality of the fold of mucous membrane that occurs at the orifice of the duct. But there was no evidence of gall-stone or any other cause which could have produced it. The probability is that the pouch was formed from one of the valvulæ conniventes, although the precise mechanism of its production is obscure. The entire absence of the folds from the dilated duodenum above the pouch may doubtless be ascribed to the distention which this portion of gut underwent in common with the stomach. In introducing the subject, Dr. Pertik makes some general remarks upon the etiology of gastric dilatation. Exclusive of congenital strictures of the pylorus, etc., he points out that the diminished power of the stomach to expel its contents may be brought about by: 1. Obstruction at the outlet—as from cicatricial or malignant strictures, hypertrophy of the muscularis or mucosa at the pylorus, polypi or tumors in the pyloric region, or external pressure on this part by tumors in the vicinity. 2. An actual loss of muscular power in the stomach, without any obstruction—as following on chronic catarrh, extensive ulceration, carcinomatous infiltration, peritonitic adhesions; and general conditions leading to loss of tone—as anæmia, typhoid fever, phthisis, etc. 3. An excessive amount of contents, as has been observed in the polyphagous, diabetics, and vegetarians; so that the pyloric orifice becomes relatively too small for the ready passage of the bulky gastric contents. The curious case related above falls, of course, under the first head, but the obstruction was in the duodenum, and not at the pylorus.—*The Lancet.*

IS INSTRUMENTAL DELIVERY A CAUSE OF IDIOCY?—Drs. Winkler and Bollaan have written a paper in a Dutch medical journal on "The Forceps as a Cause of Idiocy." They mention a case of bilateral, almost symmetrical, damage to the cortex of the brain, found in an idiot (*The Lancet*). The boy had been born with the aid of forceps. Only part of the vertex could be examined. There were no marks of the forceps, yet there were strong reasons for belief that the injury was caused by them. In another case there was still more ground for the opinion that injury had been caused by forceps. In this child, who was an idiot from birth, there were marks of the forceps on both sides of the skull corresponding almost exactly to the damage done to the brain. This coincidence was too remarkable to be accidental. Drs. Winkler and Bollaan performed necropsies on ten idiots, and examined twenty-five living idiots, of whom six had bilateral depressions in the skull. Another case was that of a woman born with the aid of forceps, an inmate of the Utrecht Asylum for four years. She was very short, being only 1.27 metre high, and small in proportion. She could make all move ments, isolated movements being difficult to her. There were but two words which she could say, and she never gave any sign of understanding what was said to her. She died at the age of sixty, and at the necropsy the brain was found to be very small. All the organs at the base of the brain, the optic nerves, olfactory nerves, etc., were found to be very small. Deep depressions were found on either side of the sagittal suture, the right side being the more indented. The brain was much atrophied. The authors believe that depressions of the skull caused by instrumental delivery, even when no fracture occurs, tend to damage the cortical substance of the brain, and that this leads to general atrophy of the hemispheres, thus producing idiocy. They are disposed to think that the use of forceps is much more frequently the origin of idiocy than is generally supposed.

STRYCHNINE AS AN ANTIDOTE IN NARCOTIC POISONING.—Dr. G. A. Gibson calls attention in *The Practitioner* for December, 1888, to the value of strychnine in antagonizing the paralyzing action of narcotic poisons upon the medullary centres. In cases of respiratory failure during chloroform or ether anæsthesia, he has also found hypodermatic injections of strychnine to be of great service.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 30, 1889.

A NEW METHOD OF OPERATION FOR THE REMOVAL OF NASO-PHARYNGEAL TUMORS.

IT is quite generally admitted at present that a majority of naso-pharyngeal growths call for operative interference. This may be either of the cutting kind, or by means of the snare, scoop, cautery, ligature, or some such procedure. Probably the cold snare and galvanic wire are more frequently employed nowadays than any of the other non-cutting methods. But, even with the recent improvements in instruments of this kind, the success attending such operations is far from being universally satisfactory. The main difficulty lies in the circumstance that essential steps of the operation are necessarily undertaken in the dark.

Mr. Thomas Annandale has devised a method of operation (*The Lancet*) intended to do away with some of the objections to surgical interference in this class of diseases. In three cases Annandale's method has been successfully carried out. The author admits that such growths have been reached through the palate by Nélaton and others, but not in the simple way presently to be described. As far as he is aware, his operations have demonstrated, for the first time, the fact that when the alveolar margin and palatal portions of the upper jaw have been divided along their centre, from before backward, and the bony septum of the nose cut through, the anterior nares having first been exposed by Rougé's plan, the two upper jaws can be separated to the extent of from half an inch to one inch, so as to give access to the posterior nares and base of the skull.

The steps of Annandale's method are as follows: 1. The exposure of the anterior nares by freely dividing the mucous membrane connecting the upper lip and upper jaws, according to the plan of Rougé. 2. The division of the bony septum of the nose along its attachment to the jaw. 3. Incising the soft parts along the middle line of the hard palate, and then sawing through the alveolar margin of the upper jaw, and through the entire hard palate along the same line. The soft palate may or may not require division in its middle line. The necessity for this depends upon the size and attachments of the growth. (In one of his cases he did not divide it; in the other two he did.) 4. The forcible separation of the two jaws, and the introduction through the gap of the finger, periosteal scraper, or other similar instrument, with the view of separating the *secondary* connections of the growth to surrounding parts. 5. The removal of the growth from its primary site of origin by forceps, sharp spoon, cold snare, or galvanic wire. (In all his cases he used strong forceps, assisted by a periosteal elevator and a sharp spoon.) 6. When the tumor has been removed, the introduction of some form of antiseptic plug, such as a plug of lint soaked in carbolic acid, and well dusted with iodoform. 7. The jaws are now brought together again, and secured by one wire suture through the alveolar margin of the bone, and two or more horsehair sutures through the soft parts of the palate wound.

In his further remarks about these operations Annandale says that, in all three cases, the patients were thoroughly anæsthetized, and during the operation the head was placed in a dependent position, resting over the edge of the operating table. In one case preliminary tracheotomy was required because the patient was unable to respire properly when lying upon his back, owing to the pressure of the tumor upon the larynx. But in the other two cases the operation was completed without any difficulty as regards the respiration or flow of blood into the air-passages. Although advocating this special method in cases which demand some cutting operation, he by no means condemns all other plans of procedure, for he believes with Sands that in cases of sarcoma, or in cases in which the attachments of the growth are extensive, the excision of the whole or of a portion of the upper jaw will give the best and most certain result.

The advantages of his method, according to Annandale, are the following: 1. It is a simple procedure, and if the growth can be removed by its aid no deformity results. 2. Should it be found that the growth cannot be properly exposed and removed in this way, the proceeding forms one usual stage of a more severe operation—namely, the removal of the upper jaw itself—and therefore it assists, and does not interfere with further operative measures. 3. From his experience of operations for the removal of naso-pharyngeal growths, he has a strong opinion that the central section, as advised, is accompanied by less bleeding than most of the other cutting operations practised.

SOME REAL OLD FOLKS.

To judge from the frequent references to old people appearing in the daily papers, from the articles on the prolongation of life in the popular magazines, and from the more or less scientific reports on the same subject in medical publications, this world of ours would seem to be passing through an epidemic of longevity second only in degree to that recorded in ancient times, wherein Methuselah was such a prominent figure.

Numerous instances have been brought out in these investigations of persons who have lived a century and upward, and many of them are so well authenticated as to disprove entirely the assertions of those who hold that human life never surpasses, or even reaches, the term of one hundred years. But these modern instances of longevity pale before those cited in the old records of two or three centuries ago. Many of these records give the dates of birth or of baptism, and of death, of the persons mentioned, and while it is not of obligation to yield implicit belief as to their accuracy, we cannot deny that they furnish us examples of long life far surpassing that usually allotted to man.

In a curious book, entitled "The Code of Health and Longevity," by Sir John Sinclair, published in the early part of this century, we find several portraits of old people, accompanied by brief biographies. Some of these histories, as that of Thomas Parr, or "Old Parr," who is said to have died at the age of 152 years, and is buried in Westminster Abbey, and that of Catherine, Countess of Desmond, who had three or four sets of (natural) teeth, and who made the journey from Bristol to London after she had passed her 140th year, are among what may be termed the classical tales of longevity, and are familiar to all students of the subject. There are others, however, which are not so well known, although making even greater demands upon human credulity.

The oldest of the worthies figured in this volume is Czartan Petratsch, *anglicé* Peter Zortan, who lived to the ripe old age of 185 years. He was born near Tameswaer, in Hungary, in 1537, and died in January, 1723. He is represented in the picture sitting beside an old ruin, his countenance expressive of the utmost dejection, and looking wearily at a pot in which he is boiling his dinner, for which, however, he evidently has but little appetite. His whole appearance is indicative of the most profound disgust with the world, with whose miseries and disappointments he had had such a long experience.

The climate of Hungary would seem to have been conducive to longevity, for we find the portraits of two other old people who lived and finally died in the same district. These were John Rovin and his wife Sarah. At the time the picture was taken their ages were 172 and 164 years respectively, but how long they survived this period is not known. Mrs. Rovin is represented sitting upon a bench in the open air, while her husband is bringing her something that might be a bunch of bananas, a bundle of fagots, or the head-dress of an Indian chief. They both look rather weary and have lost somewhat of the freshness of youth. Lying beside Sarah is an antique cat that looks as if she might have been a good-sized kitten when the parents of this aged couple were children. They had four children living at that time, the youngest of whom was a promising lad of 116 years. Time had dealt less gently with the old lady than with her spouse, for while she was in reality eight years younger than her husband, her picture makes her appear several centuries older.

Scotland seems also to have been the home of many centenarians, though but one of them could rival these Hungarians in his length of days. Among these were Isobel Walker, who trod this earth for 112 years, and Peter Garden, who tilled the Lord's vineyard for thirty-one years over and above a century. John Taylor lived a bachelor for sixty years, then took to himself a wife and was rewarded, or punished, for this action by seventy-two years of added existence. The oldest Scotchman, of whom there is any record, was Bishop Kentigern, afterward beatified under the name of St. Mungo, who founded the Bishopric of Glasgow, and who lived to the age of 185 years. The record of his age and of his place of interment is presented in a Latin couplet quoted in Spottiswood's "History of the Church of Scotland."

Very little is said about the habits of these people, to serve as a guide for those who would care to secure an equally long lease of life. Most of them, however, are reported to have been God-fearing persons of a placid disposition and simple tastes, working hard without worry, satisfied with their lot, eating moderately, and sleeping soundly. And, although nothing is said on this point, we dare affirm that they never smoked cigarettes.

THE DURATION OF LIFE IN CANCER OF THE BREAST.

THE average duration of life in cases of mammary carcinoma is very variously estimated by different observers, ranging from 28 to 55 months in those not operated upon, and from 32 to 53 months in cases in which the new growth has been removed by the knife. Thus Gross, whose statistics are among the least hopeful, gives as the average duration of life, of those in whom the disease had been permitted to run its course, 27.1 months, and of those operated upon about 39 months. Sibley's figures for the same classes of cases are 32.25 and 53.2 months. Baker makes the average, for cases uninterfered with by operation, 43 months, while Paget's estimate for the same class of cases is 55 months.

By far the most hopeful figures which we have seen are some given by Mr. W. R. Williams, in *The Lancet* of January 12, 1889. He has recorded and tabulated all the fatal cases of cancer under treatment at the Middlesex Hospital during the last six years, with the result that the average duration of life, dating from the time when the disease was first noticed, was 60.8 months for those who had undergone operation, and 44.8 months for those in whom the disease ran its natural course. The longest duration of life when the breast was amputated was 297 months, and when no operation was performed, 194.7 months. The author thinks that his statistics justify surgeons in taking a less despondent view of mammary carcinoma than is ordinarily taken.

PULMONARY CONSUMPTION AS A NEUROSIS.

SOME French writers are very fond of referring many, and apparently dissimilar, diseases to one common pathological state, which they denominate herpes, and which they regard as the underlying condition of numerous affections looked upon by the rest of the world as independent diseases. The affections thus classified are many and various, even pneumonia being included among the herpetic diseases; but it has been left to an American, Dr. Thomas J. Mays, of Philadelphia, to extend this theory to, it would seem, its utmost limits, for he is, we believe, the first who has ever attempted to squeeze tuberculosis into this procrustean mould. It is true that a few writers, chiefly English and French, have more or less haltingly hazarded the opinion that phthisis is a neurosis; but to Dr. Mays certainly belongs the honor of having elaborated this theory and of having fortified it by an array of elaborate and ingenious arguments. Two of a course of evening lectures, given by the Faculty of the Philadelphia Polyclinic during the past winter, were devoted by Dr. Mays to a development of this theory. These were subsequently published in the *Therapeutic Gazette* in November and December, 1888. Stated briefly, the lecturer's belief concerning phthisis is that it is not a local disease, but that it is essentially a neurosis of the peripheral nerves. This peripheral neurosis induces a herpes of the vagi, giving rise to lesions in the lung similar to the cutaneous manifestations

of herpes zoster of other nerves. The grave consequences of pulmonary herpes are owing, not to the nature of the lesions, but to their seat. When located on the skin the morbid products are easily gotten rid of, but in the lungs they are pent up, and finding no ready exit work destructive changes in the tissues.

The main argument upon which the author bases his peculiar theory is the somewhat fallacious one that certain neuroses are frequently found accompanying consumption, the severity of their manifestations being often in inverse proportion to the progress of the pulmonary lesions. Among the symptoms which he instances as evidences of a neurotic condition are fatigue, loss of appetite, emaciation, hoarseness and aphonia, dyspnœa, sweating, diarrhœa, hæmoptysis, œdema, and thoracic pains. He cites a large number of cases intended to show the alternation in members of the same family of pulmonary tuberculosis and nervous affections, and also the association in the same individual of consumption and certain well-recognized peripheral neuroses.

It is certainly rather startling in this age of microbes to find a physician of ability and large experience arguing in support of the neural origin of tuberculosis, for we assume that he does not deny the identity of the tubercular affection, whether it be in the lungs or in the kidneys, joints, glands, or any other organ of the body, although his thesis deals only with the pulmonary location of the disease. And though we fear Dr. Mays will not live to see his theory accepted by the profession, we can nevertheless commend his courage and recommend his paper to the thoughtful consideration of all who can respect the convictions of an earnest thinker, however little they may be inclined to agree with him.

AN EARLY SIGN OF ENDOCARDITIS.

EVERY one who has watched a case of acute articular rheumatism and has noted the appearance, during its course, of valvular lesions of the heart, must have wished for some means whereby the intercurrence of endocarditis might be detected at an early period. Usually the first sign of this complication is a murmur at one or other of the cardiac orifices, an indication that the valves are already involved in the inflammatory process.

Dr. Duclos, of Tours, writing in the *Revue Générale de Clinique et de Thérapeutique*, January 17, 1889, records a fact of his experience, in regard to commencing endocarditis, which may possibly be of value as an aid in the early recognition of this affection. While in charge of a military hospital he chanced to have a large number of young soldiers suffering from acute articular rheumatism under his care. One day, while listening to the heart-sounds of one of these patients, his finger being at the same time on the radial pulse, he was struck with the want of synchronism between the ventricular contraction and the pulsation at the wrist, the latter being delayed about two-thirds of a second. The following day a systolic apex murmur was heard. Thinking that this retardation of the radial pulse might have some significance in connection with the subsequent development of endocarditis, he took pains to note its occurrence in other cases, and found that it was followed by a murmur at the end of from twenty-four to thirty-six hours in every instance. These observations were extended over a period of several years, and were confirmed in a number of cases by Professors Parrot and Potain.

The author has no conclusive theory to offer in explanation of this phenomenon, but he thinks that it is probably due to a weakening of the muscular fibres subjacent to the endocardium. He compares it to the weakened respiratory murmur frequently observed at the beginning of a pleurisy a few hours before a friction-sound is developed or effusion takes place. It would be interesting to learn whether this want of synchronism is present in the beginning of endocarditis arising in the course of other diseases, but the author has few observations bearing on this point to record. He has noted it, however, in two cases of typhoid fever and in three of erysipelas, in which endocarditis subsequently developed.

Dr. Duclos draws some practical conclusions, in regard to treatment, based upon the early recognition of the affection, and he believes that he has succeeded in arresting the disease, in certain cases, before irreparable injury had resulted. His plan is to apply immediately a large flying blister over the præcordial region, or, in default of this, a mustard-plaster, dry cups, or leeches. He increases also the dose of the remedy that is being at the same time given for the rheumatism. Of course, a strict enforcement of recumbency is also indicated.

When we consider the importance of an early diagnosis of endocarditis, and the possibility of arresting the disease if detected in its incipiency, this alleged premonitory symptom of the affection is worth testing in order to determine the amount of practical utility that it may possess.

PROFESSIONAL PATENTS VERSUS A LIBERAL PROFESSION.

AT a meeting of the New York Odontological Society, held at the Academy of Medicine on the evening of March 19th last, a paper was read by Dr. H. C. Meriam, of Harvard University Dental School, entitled, "Professional Atmosphere and Morals; or, Patents and Secrets versus a Liberal Profession." Statements made by the essayist, and by those who discussed the subject, reveal a condition of things in dentistry which, if understood, can hardly fail to impress the minds of physicians with the possibilities involved in professional patents when followed to their legitimate conclusions. He said that dentistry was so fettered by patents obtained by dentists, and held by persons or corporations, that it could not be called free, and that it could lay no just claim to being a liberal profession so long as dentists patented their devices and sold them to manufacturers and others, who held them either to maintain a monopoly of their manufacture and sale, or for the purpose (often practised) of preventing their being made at all, when their use would conflict with the sale of instruments or devices out of which more money could be made. Quotations were made from two dentists, one of whom said, that "so long as dentists who patent their inventions and make money out of them are honored as leaders in schools, and by societies, so long will dentistry remain a trade, and I shall be ashamed to use my dental degree;" and another had written, "we are fast becoming a mere tender to a trade association, and about all the liberty left us is the right to buy what the association allows its members to sell."

The claim was made that patents, instead of being stimuli to the improvement of instruments and appliances, were an actual hinderance, because no one could make, use, vend, or improve anything covered by a patent without the permission of the person owning the patent; and that the inhibitory power thus conferred was more sought for than the privilege of making or vending. The charge was made that dentists were selling the control of instruments to manufacturers, and also the control of processes and operations to companies who wish to license, thus providing an upper and nether millstone between which the great body of the profession can be ground exceeding small. College professors, and editors of journals professedly devoted to the interests of the profession, were accused of working students and the profession for what they could make out of them. The speaker claimed that patents and secrets were a falsehood in a liberal profession, and among letters read by him sustaining his position were one each from Drs. Oliver Wendell Holmes, David W. Cheever, and H. P. Bowditch.

The speaker was enthusiastically applauded, and the sentiments expressed were endorsed and commended by Drs. W. H. Dwinelle, E. A. Bogue, S. G. Perry, and J. Morgan Howe, of New York; C. D. Cook, of Brooklyn; C. N. Pierce, of Philadelphia; D. B. Parmele, of Hartford; Potter, of Boston, and others.

One well-known dentist said that it was one of the greatest regrets of his life that he had ever taken out a patent, and that he would never commit such a mistake again. There was no audible dissent from the conclusions of the essayist.

HEADACHE AND ITS RELATION TO THE RETENTION OF URIC ACID.

THE etiology of many forms of headache is still quite obscure. Dr. A. Haig[1] maintains that one variety of periodic headache is directly due to the retention of uric acid in the system. The usual sequence of events, according to him, is as follows:

There is a time (say seven to ten days) of good general health, active nutrition, and bodily activity, with plus formation of uric acid and urea, and concomitant rise in acidity. As acidity rises, uric acid comes to be retained, and at the end of four or five days several grains may be regarded as stored up in the liver and spleen. Then come dyspepsia, gastro-intestinal catarrh, and hepatic congestion (and Dr. Haig is not by any means certain that this hepatic congestion and gastro-intestinal trouble may not be the direct result of the accumulation of uric acid in the liver and spleen). These quickly result in general diminution of absorption and nutritive changes, with lessened formation of uric acid and urea and a fall in acidity; and lastly, as the result of this falling acidity, there comes a rush of the stored uric acid into the blood and the headache begins.

Such a sequence may be seen to some extent in the figure that accompanies his paper on headache ("Transactions," 1887), for there the urea drops from 561 grains to 363 grains in the four days that immediately precede the headache. Although acidity was not estimated in this instance there can be no doubt that it followed and shared in the fall of urea to a large extent. Such a sequence explains the periodicity of this kind of headache, and the way in which it comes to occur every week or ten days for many years, varying only in degree with the corresponding variations in nutrition. It is also evident that any causes which affect digestion will influence the attack in one of the above ways; while all causes of debility, by weakening the nerve-centre on which the uric acid acts, will render it more sensitive (the reverse of the action of bromides) and the attacks more frequent. A knowledge of these facts gives him almost complete power either to cause or cure this headache in himself and other sufferers.

The good effects of salicylic acid, and the salicylates generally, in this variety of headache, are due to the circumstance that they facilitate the excretion of uric acid, and thus prevent the retention of excessive amounts within the body.

[1] Effects in Health and Disease of some Drugs which cause Retention of Uric Acid, etc. Reprinted from Medico-chirurgical Transactions. London, 1888.

DEATH IN THE SCHOOLS.

THE death of one of the public-school teachers of this city from typhoid fever, recently, has justly excited a great deal of criticism, and will lead, we trust, to a more careful examination of our public-school buildings.

At the same time we would call attention to the fact that it is in nowise proved, as yet, that the typhoid fever from which the patient died was contracted in the school building. Typhoid fever is a specific disease, and infects the system almost exclusively through food and drink taken into the stomach. The inhalation of poisoned air may weaken and predispose to the disease, but only in rare instances does it cause the specific fever. Hence the home surroundings of a patient always come in for special investigation. We venture to suggest that the late Miss Gibbs, the teacher in question, did not actually contract the disease in the school-house, despite the abominable and inadequate ventilation of that building.

IMPORTING DOCTORS.

THE *International Journal of Surgery* publishes an advertisement which recently appeared in the *Allgemeine Medicinische Central-Zeitung* of January 26, 1889, announcing a vacancy in the house-staff of the German Hospital of this city. The qualifications and emoluments are stated. The *Journal* justly, we think, protests against sending to Europe for house physicians to our hospitals. The German Hospital is supported by American citizens and American money. Its staff is even paid a liberal sum, a thing not done in most hospitals. There are plenty of competent American graduates who speak German, and who would be glad of the advantages of a city hospital.

THE CAUSES OF DEATH AMONG THE GOUTY.

DR. EDWARD CASEY has prepared some tables regarding the causes of death among the gouty. The data were obtained from the Collective Investigation Committee, and bear upon the conditions in Great Britain chiefly. The number of cases analyzed was 2,399, of which 529 were of gouty persons. The deaths all occurred in persons above the age of forty. Dr. Casey also classifies the cases in accordance with the drinking habits, *e.g.*: Class

B = abstemious; Class C = moderate drinkers; Class D–E = the free drinkers.

The following table summarizes the results of the work very well. It shows the percentage proportion of deaths from several causes to deaths from all causes in the same classes:

	B.		C.		D–E.	
	Gout.	No gout.	Gout.	No gout.	Gout.	No gout.
Bright's disease	8.9	2.8	8.4	2.9	10.3	5.9
Heart diseases	12.5	15.8	11.4	12.0	17.1	12.2
Apoplexy and paralysis	13.9	13.2	16.2	11.1	15.6	10.8
Cirrhosis of liver	....	....	1.2	1 0	6.1	6.7
Malignant disease	5.0	6.2	4.8	6 5	5.0	4.6
Bronchitis	11.9	13.0	13.2	13.3	10.3	9.3
Pneumonia	5.0	6.2	10.2	8.4	5.0	11.5
Phthisis	2.0	9.3	3.0	8.9	3.8	12.5
Old age	15.8	13.5	8.4	10.4	3.4	3.0

Dr. Casey shows by this table that Bright's disease is closely related to the gouty diathesis. It appears to be nearly three times as frequent a cause of death among the gouty as among the not gouty, at all ages alike, and both in the temperate and the intemperate, the disproportion being, however, somewhat less in the latter class.

Regarding heart disease he says: "The effects of gout in the production of heart disease appear to be strongly marked during the period of middle age, but not in the later years of life. It seems probable that heart disease of gouty origin generally runs its course before old age is reached. The frequency of cardiac disease among the not gouty shows no special connection with habits of intemperance; but it must be borne in mind that the relative mortality of the intemperate is very much greater than that of the abstemious."

Apoplexy shows the same tendency as Bright's disease and heart disease, but in less degree.

Cirrhosis.—The data concerning this disease are scanty, but no relationship to gout appears.

Of malignant disease the same may be said.

Bronchitis seems to be uninfluenced either by gout or by intemperance.

Pneumonia and the diseases grouped with it appear to be less common among the gouty, but to be more fatal among the intemperate classes. The category is, however, a miscellaneous one, and not improbably includes some tubercular cases.

Phthisis is shown to be very considerably less common as a cause of death among subjects of gout.

Finally, it is shown that the gouty habit in the case of the temperate is no hinderance to the prospect of attaining extreme old age.

ARSENICAL POISONING FROM GREEN CANDLES.—At a children's party in London, last Christmas, a number of the little guests, as well as several of the adults, were seized with curious and inexplicable symptoms, which could not be traced to the ingestion of any particular food or liquid of which they had partaken. Attention was then drawn to the candles on the Christmas tree, many of which were green, and these, when submitted to analysis by the county analyst, proved to contain Scheele's green, the red candles, moreover, being colored with vermilion.

News of the Week.

SOUTH CAROLINA MEDICAL ASSOCIATION.—The next Annual Meeting of the South Carolina Medical Association will be held in Charleston, S. C., on Wednesday, April 24, 1889.

REOPENING OF ST. ELIZABETH'S HOSPITAL.—Judge Barrett's recent decision in favor of a majority of the members of the Congregation of the Third Order of St. Francis, which owns St. Elizabeth's Hospital in West Thirty-first Street, in the proceedings against Mother Mary McNulty, who opposed the corporation, will have the effect of reopening the hospital on April 15th. St. Elizabeth's is the only hospital in the city where a physician can send his patient and treat him himself. Any reputable physician can, on proper introduction, avail himself of this privilege, and Sisters will be detailed to carry out his instructions with regard to his patient. Sister Mary Joseph will conduct the hospital when it is reopened. The institution was founded in 1870 by members of the lay order of St. Francis. Two years ago, under Mother Mary McNulty, who was an aged woman, the institution became disorganized, and Archbishop Corrigan was asked to interfere, and two regular Franciscan nuns were put in as assistants to Mother McNulty. She fancied that they were trying to secure possession of what she considered her property, and began suit to restrain them.

THE ANNUAL MEETING OF THE NATIONAL ASSOCIATION OF RAILWAY SURGEONS will be held at St. Louis, Mo., on Thursday and Friday, May 2 and 3, 1889. The prospects are that this will be one among the largest gatherings of medical men ever assembled in this country. Dr. W. B. Outten, of St. Louis, is the Chairman of the Committee of Arrangements, and everything will be complete for the accommodation of the surgeons. Any information desired can be had by addressing the Secretary, C. B. Stemen, M.D., Fort Wayne, Ind.

MISSISSIPPI STATE MEDICAL ASSOCIATION.—The Annual Session of the Medical Association of the State of Mississippi, for the current year, will be held in the city of Jackson, commencing on the third Wednesday in April (17th), at twelve o'clock noon, and continue for three days.

STATISTICS OF ABDOMINAL AND PELVIC SURGERY.—In Paris, M. Péan, in presenting to the Academy of Medicine the sixth volume of his "Clinical Surgery" (St. Louis Hospital), said that the third part contained statistics of 182 gastrotomies performed by him, from January 11 to December 31, 1886, which brings up to a total of 945 such operations from 1864 to 1887. Of these 182 operations, 71 were for the removal of tumors of the ovaries, tubes, and broad ligament (68 by abdominal and 3 by vaginal operation), and only one of these failed; 90 for uterine tumors—23 hypogastric (3 deaths), and 67 vaginal (1 death). The remainder were distributed as follows: For tumor of mesentery, 1 (fatal); of peritoneum, 4 (1 death); of intestine, 1; of abdominal wall, 1; of kidney, 4 (1 death); of liver, 2; of pelvis, 7 (3 deaths); of iliac fossa, 1 (fatal). Thus there was a gross total of 170 successful and 12 unsuccessful operations.

DISTRIBUTION OF THE HOSPITAL COLLECTION FUND.—It is announced that the collection for the year amounted to $52,033.40, as against $50,449.15 the year before. Of this amount $5,502.75 was designated, and $46,530.65 undesignated. Reserving $2,530.65 to cover part of the expenses of last year, as well as the expenses of the current year, there remained $44,000 of the general fund, which was distributed on the basis of free work as follows:

	Number of Days of Free Work.	Rate 12.30 Cents per Day per Patient.
1. Mount Sinai	59,896	$7,365 80
2. St. Luke's	53,768	6,541 76
3. German	39,095	4,807 51
4. Ruptured and Crippled	36,586	4,500 05
5. St. Mary's	18,618	2,246 89
6. Home for Incurables	17,888	2,198 62
7. House of Rest	13,942	1,710 27
8. Holy Comforter	12,339	1,512 51
9. Colored	11,962	1,471 32
10. Montefiore Home	10,456	1,286 08
11. Skin and Cancer	9,162	1,125 92
12. Manhattan Dispensary and Hospital	8,818	1,081 62
13. Woman's	7,972	970 27
14. French	7,857	960 53
15. Orthopedic	7,727	950 42
16. Manhattan Eye and Ear	7,171	977 89
17. New York Eye and Ear Infirmary	6,527	802 82
18. New York Infirmary for Women and Children	6,471	795 93
19. New York Ophthalmic	6,303	775 26
20. Post-graduate	4,963	607 58
21. New York Medical College and Hospital for Women	4,807	591 26
22. Convalescent Home	3,112	381 34
23. New York Ophthalmic and Aural	2,285	282 10
Special expense deduction		156 25
Totals	357,725	$44,000 00

THE PATERSON (N. J.) GENERAL HOSPITAL has received a bequest of $10,000 by the will of the late Mr. Samuel Pope.

A NEW DIAGNOSTIC SIGN OF HERNIA.—Dr. Multanovski suggests the addition of a new diagnostic sign to the classical method of diagnosing abdominal hernia. Having made observations on one hundred and fifty-two cases of hernia in Professor Bogdanovski's wards, he states that in all these, when the finger was passed up into the abdomen, a more or less tightly stretched strap-like band could be detected connecting the contents of the sac with those of the abdomen.—*Lancet.*

CARL ZEISS, the widely known manufacturer of lenses, microscopes, and microscopical instruments, has lately died at Jena, aged seventy-three years.

AN AMERICAN HOSPITAL is one of the features of the city of Mexico. All English-speaking persons that apply are admitted. Regular contributors to the hospital, who subscribe not less than $1 monthly, and Americans without means of support, are entitled to attendance and medical treatment in the general ward, free of all charge. Other persons may enjoy the privileges of the hospital on equitable terms, and private rooms are provided for such as desire them.—*Journal of American Medical Association.*

HISTORY OF THE MEDICAL PROFESSION IN CANADA.—The descendants of the early doctors of Upper Canada will be interested to learn that there is being prepared an historical account of those pioneer practitioners, by Dr. Canniff, of Toronto, the author of "The Settlement of Upper Canada."

ANTERIOR METATARSALGIA is the name given to a painful affection of the forepart of the sole of the foot and the metatarsal joints. It is described by Dr. August Pollosson, of Lyons, France, and is evidently much the same thing as the Luxation Neuralgia described by Dr. Morton, of Philadelphia, and under the head of Acroneuroses by Dr. Dana, of this city. An annotation in *The Lancet* calls attention to the description of a case by Dr. Edmond Roughton, who also shows how easily some forms of the trouble are cured. He writes: "A medical man, aged thirty-three, complained to me that for eighteen months he had suffered from attacks of burning pain in the fore part of the sole of the left foot. The pain occurred several times a week, and was usually brought on by prolonged standing or by walking any considerable distance, and was sometimes so severe as to cause him to remove his boot and grasp the sole of his foot in his hand. On examining his foot, I found that the transverse arch formed by the heads of the metatarsal bones had sunk, so that a distinct convexity replaced the concavity normally found in this situation. I advised him to practise the gymnastic exercises so beneficial in ordinary flat-foot—viz., to take every opportunity of raising the body on tip-toe, and so strengthen the tendons and muscles of the sole of the foot. Since resorting to this treatment (now nearly a month) he has been quite free from pain.

THE LABORATORY OF HYGIENE OF THE UNIVERSITY OF PENNSYLVANIA has been promised $25,000, if another $25,000 can be raised by the University.

TRAVELLING WITH CONSUMPTIVE PATIENTS.—The sanitary authorities of New South Wales and Victoria have signified their intention of communicating with the various steamship companies with a view to action being taken to avoid the possibility of healthy and consumptive patients occupying the same cabin.

SIX LAPAROTOMIES IN ONE WOMAN.—The *Gazetta Medica di Torino* records the case of a woman, fifty years of age, who had submitted to laparotomy upon six different occasions at the hands of Professor Franzolini. The operations were performed between June, 1879, and April, 1887. The first was in consequence of fibro-cystic disease of the uterus. A triumph of surgery such as this, we may well believe, is without precedent, and the most satisfactory part of the case is that the patient has since the last operation been in the enjoyment of good health. So does she deserve her reward!—*Medical Press.*

THE TANNIN TREATMENT OF PHTHISIS.—Dr. E. Houzé, of the Hospital St. Jean, Brussels, after having tried the tannin treatment on all his phthisical patients for the last year and eight months, states as the result of his observations, that it gives excellent results in all stages of the disease, and especially in the condition where cavities exist. Indeed, he has no hesitation in declaring that of all the different kinds of treatment for phthisis which he has tried this has given by far the most encouraging results. The dose he employs ordinarily is fifteen grains, which quantity is taken three times a day. It is, as a rule, well borne; where this is not so, it is ordered to be taken with meals. After the first few days, the expectoration and the sweats diminish, the cough decreases, and in many cases the appetite undergoes a marked improvement. The majority of the patients suffered from some slight degree of constipation, though in some this feature was sufficiently marked to require treatment; while others, again, suffered from diarrhœa.

THE SPRING'S WORK IN CINCINNATI.—A correspondent writes that the Miami Medical College has graduated 22 students; the Cincinnati College of Medicine and Surgery, 32; the Medical College of Ohio, 86; the Pulte Medical College (Homœopathic), 24; the Ohio College of Dental Surgery, 65; and the Cincinnati College of Pharmacy, 18. Totals: Doctors, 164; dentists, 65; druggists, 18.

MEDICAL GRADUATES.—Following are the numbers of graduates from schools that have recently closed the session of 1888–89: Baltimore Medical College, 21; Starling Medical College, 28; University of Nashville and Vanderbilt University, 98; Baltimore College of Physicians and Surgeons, 67.

THE EMPEROR WILLIAM OF GERMANY has forwarded the modest sum of $150 for the benefit of the new City Hospital of Baltimore.

EXHIBITS AT THE NEXT MEETING OF THE AMERICAN MEDICAL ASSOCIATION.—The Chairman of the Committee of Arrangements, Dr. Stover, announces that the following classes of applications will be entertained: 1. Medical books and stationery, charts and diagrams, busts, portraits, engravings, photographs, etc. 2. Hospital and ambulance plans and models. 3. Surgical instruments and supplies, general and special (gynecic, obstetric, orthopedic, laryngeal, otic, ophthalmic, dental, etc.). 4. Microscopes, analysis outfits, and electro-galvanic apparatus. 5. Pharmaceutic products. 6. Rubber goods applicable to medicine and surgery. 7. Invalid furniture. 8. Invalid foods. 9. Sanitary appliances, as ventilators, filters, w. c. basins, traps, and similar necessities, and disinfectants.

THE DEATH OF DR. WILLIAM L. WARDWELL, at Tucson, Ariz., on March 21st, brought to an untimely close a most promising career. Dr. Wardwell graduated from Bellevue Medical College in 1878, he spent several years at the Vienna General Hospital, and at Leipsic in Cohnheim's Laboratory of Pathology, Returning to New York—his home—he entered Bellevue Hospital, serving for eighteen months on the surgical side. He was later appointed instructor in surgery in the New York Polyclinic, a school of clinical medicine and surgery for physicians, where he worked with great credit until prostrated by pulmonary consumption. He was the author of several articles in "Wood's Handbook of Medical and Surgical Reference," and other valuable papers.

DEATH OF PROFESSOR DONDERS.—Professor François Cornelius Donders, one of the most distinguished oculists that ever lived, died at The Hague on March 24th, aged seventy. He was born in Tilburg, Brabant du Nord, May 27, 1818. He was graduated from the Military Medical School of Utrecht, of which he soon afterward became a professor. He retained that position only a short time, as he accepted the chair of Physiology and Histology in the University of Utrecht. He devoted himself particularly to diseases of the eye, and wrote many articles upon his favorite subject for European scientific periodicals. In 1863 he obtained a grant from the Government sufficient to build and equip a physiological laboratory. He was made a correspondent of the Paris Academy of Medicine in 1873, and of the Paris Institute in 1879. Fuller details of his life and work will be given later.

A NEW TREATMENT OF ANEURISM.—The Glasgow correspondent of *The Lancet* gives an account of a demonstration by Dr. Macewen of a new method of treating aneurisms. Needles are passed into the sac in such a way as just to touch the lining of the opposite wall. The oscillation of the needles causes a succession of fine scratches "on the inner surface of the endothelium, irritating it slightly and leading to the proliferation of leucocytes," which develop into a white, fibrous mass.

CHLOROFORM AS AN INTERNAL REMEDY.—Dr. Stepp of Nürnberg, noting the observations of Salkowski on the disinfecting power of chloroform water, determined to make trial of chloroform internally in a considerable number of diseases. It may here be remarked that the use of chloroform in aqueous or spirituous solution is less common in Germany than in this country, where the familiar so-called "æther chlor." forms a portion of a very large number of prescriptions. In gastric ulcer, Dr. Stepp gave chloroform (fifteen grains in a five-ounce bismuth mixture) with great effect, and believes this to be due to its disinfecting, astringent, and stimulating properties. In various affections of the mouth and throat—as follicular pharyngitis, catarrh of the pharynx, gingivitis, and diphtheria—washes and gargles containing chloroform proved very beneficial. In one case of severe psoriasis of the mucous membrane of the mouth, which had been unsuccessfully treated by several medical men, chloroform water effected a complete cure. Two cases of pneumonia, treated with chloroform, did so well that Dr. Stepp means to make a further trial of it in this disease. Perhaps the most encouraging results were obtained in cases of typhoid, though only six of these were thus treated.—*The Lancet.*

NAPHTHOL AND CAMPHOR IN TUBERCULOUS ULCERATIONS.—At the Société de Thérapeutique M. Feuret spoke on the treatment of tuberculous ulcerations by naphthol and camphor. Two parts of camphor to one of the naphthol form a syrupy mixture of easy application; the ulcerations are touched by means of a brush, and they quickly assume a healthy appearance. A few cases of diphtheritic ulcerations were successfully treated by the same application.

THE best process of embalming, according to the *Medical Press and Circular*, is called the "Brunelli process." The circulatory system is cleansed by washing with cold water till it issues quite clear from the body. This may occupy from two to five hours. Alcohol is injected so as to take out as much water as possible. This occupies about a quarter of an hour. Ether is then injected to abstract the fatty matter. This occupies from two to ten hours. A strong solution of tannin is then injected. This occupies for imbibition from two to ten hours. The body is then dried in a current of warm air passed over heated chloride of calcium. This may occupy from two to five hours. The body is then perfectly preserved and resists decay.

ANTIPYRIN IN CHOREA.—Professor H. C. Wood highly lauds antipyrin for chorea; in some cases he has been able to secure complete cessation of the convulsive movements inside of a week, or at most two or three, while the average duration under arsenic, etc., is from sixty to ninety days.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN OPHTHALMOLOGY AND AURAL SURGERY.

Stated Meeting, February 18, 1889.

OREN D. POMEROY, M.D., CHAIRMAN.

DISCUSSION ON CATARACT.

DR. HERMAN KNAPP opened the discussion with a paper. At the Seventh International Ophthalmological Congress, 1888, of two hundred and fifty members only five warmly advocated extraction of cataract without iridectomy. It seemed time to base the discussion of this question on experience rather than on argument. His own experience was given before forming conclusions. He had already published a series of 117 cases of extraction, only 17 of which were with iridectomy. The present paper contained a series of 113 cases, 100 without, and 13 with, iridectomy, operated upon between the spring of 1887 and December 29, 1888. He had made some changes in the technique of the operation. During a large experience with solutions of bichloride of mercury he had found irritative effects now and then from its intra-ocular injection in strength of $\frac{1}{10000}$, which had led him to abandon its use altogether for Pamard's solution, or more often, a three per cent. solution of boracic acid. The solution should be lukewarm, for when cold it was liable to cause sudden movement of the eye.

In about twenty-five cases he opened the anterior capsule with the knife on its passage through the anterior chamber, which was easily done when the anterior surface of the lens was convex and the pupil slightly dilated. But if the pupil were narrow the point of the knife might scrape the iris or engage in it on the opposite border, in which event it should be withdrawn until the iris became sufficiently disengaged, and then passed rapidly through the anterior chamber. But a section in this manner was evidently more difficult than when the knife remained in its original plane. In the operation just described, the advantage of the narrow Graefe knife was demonstrated better than on any other occasion. Collision with the iris and undesirable counter-puncture could be easily corrected, but thus far he had not exsected a piece of the iris by opening the capsule in this manner. The method was old, but had lately been revived by Galezowski and others.

Dr. Knapp recommended the continued use of the upper section, not only on account of its operative advantages, but also on account of the better chances which it gave of preventing collapse of the iris and escape of the vitreous. When the eye looked forcibly down the section gaped, and he, therefore, made it a rule to avoid downward position during the whole manipulation, but especially during the readjustment of the iris and washing out the anterior chamber, lest the iris and vitreous fall into the gaping wound. He also cautioned the patient, while bandaged, not to look down to his feet, but to hold the eyes up in the position of repose during sleep. In three of the cases there was escape of the vitreous. He had been very careful in cleansing the pupillary area, yet in a few cases a moderate amount of membrane was left, but good sight was obtained in all.

In one case acute mania disappeared in a day after the eye had been left without the bandage. In one case the eye not operated upon contracted an intense epidemic acute conjunctival catarrh on the fifth day, but careful bandaging kept the inflammation from the opposite eye. There was death from complication in one case, nine days after a normal extraction and undisturbed recovery therefrom. In one case of hypermature cataract in a man thirty years of age, on the thirteenth day of recovery, the opposite half of the visual field became defective, the defect being caused by intra-ocular hemorrhage. It slowly disappeared in the course of three months. There was posterior synechia in many cases, all filiform, and did not materially obstruct the pupillary area. There was gelatinous exudation in two cases, recovery good. The pupil was slightly oval in a few cases. Incarceration of the iris, anterior synechia in two cases, but no disturbance of vision. In six cases there was prolapsus of the iris. In the fifth of these an inordinate quantity of corrosive sublimate, $\frac{1}{1000}$, had been injected, resulting in pain the entire night, and final loss of the eye from iridocyclitis. In his first series of 100 cases without iridectomy, prolapsus of the iris occurred in 12 cases; in this series only in 6, and of this number 5 occurred in the first 50, and only 1 in the second 50. He felt convinced from recent operations that secondary prolapsus of the iris, just as secondary hemorrhage into the anterior chamber, was of traumatic origin in almost all cases, if not in every one. Its prevention depended on careful nursing. Carrying the hand to the itching eye, doubtless, had often been the cause of accidents. Dr. Knapp thought that complications of simple cataract extraction could be reduced almost entirely to accidents. Galezowski believed that prolapse was mostly produced by premature opening of the eye by the surgeon. Since he kept the eyes closed for six days he had had no more herniæ.

Of Dr. Knapp's 100 cases there had been complications of the cataract in 13. Expressing the results as to vision in the customary manner, primary S. was good in 91 cases; moderate in 8; failure in 1. Ultimate S., good in ninety-seven per cent. of the cases; moderate in two per cent.; and failure in one per cent. Comparing the primary and ultimate vision in his tables, the difference was great. In the column of primary vision there was not one case with S. 20–20, while in the second column, that of ultimate vision, there were 30 cases with S. 20–20, and the moderate results had been reduced from eight per cent. to two per cent. The cause of the gain in ultimate vision was subsequent division of the capsule, which was done in 74 cases. It would have been done oftener had he not included recent cases in his statistics. In none of these cases was vision rendered worse.

His tables showed primary vision one-fourth the normal standard, while the ultimate was fifty-seven per cent. When it was remembered that a number of cataractous eyes were otherwise diseased, this result seemed remarkable, and the conclusion was that simple extraction was both the best and the safest method of removing cataracts.

DR. GRUENING continued the discussion, and said that when he first saw this method employed in Paris, 1885, he was struck by the fact that, after the operation the eye looked much different from its appearance after his own method of operating; the wound was hardly visible, the pupil was central. He also then saw injections made into the anterior chamber, but he had long before that been accustomed to inundate the eye with a saturated solution of boric acid after cataract operations, and thus, with gentle manipulation, could remove the diluted cortical masses quite easily. On his return he began to extract cataracts without iridectomy, and had now succeeded in 36 cases, while in 12 the iris had to be cut. At first he used a four or six per cent. solution of cocaine, and instilled it into the eye fifteen minutes before the operation which he thought had an unfavorable influence and made prolapsus of the iris more likely to occur. He had, therefore, changed to a two per cent. solution, and began cocainization five minutes before operating, which produced sufficient anæsthesia. After the operation he instilled a few drops of a six per cent. solution of cocaine, which did more to prevent prolapsus than esserine. He did not like to perform a secondary operation if it could be avoided. It was possible to remove a hypermature cataract with the capsule.

Dr. Gruening did not favor the method of making section of the cornea and of the capsule together. It was

necessary to change a very simple section or operation into a very complicated or difficult one. As Dr. Knapp had described it, it was necessary to move the knife in three different planes. But he had not yet seen the operation done. He did not any more dread the cystotome, since it was his custom to boil all his instruments before using them. In conclusion he placed himself among those who were advocates of the simple operation. He had performed it a good many times, successfully in all. Although he had been obliged to cut the iris twelve times, the patients did well.

Dr. David Webster had done the simple operation in all cases, with a few unavoidable exceptions, for two years. He liked it much better than the operation he had employed previously, the modified Graefe. He always used the speculum, and preferred Graefe's right and left; the fixation forceps were applied at the lower margin of the cornea, pushing down a little before cutting; he preferred the Veis knife, with which the danger of the iris falling before the instrument was reduced to a minimum. It happened to him in only three cases out of forty-two. Before beginning to operate it was extremely important to turn over the lids and wash off the palpebral conjunctiva very thoroughly. He employed Pamard's fluid, but he was not sure that sterilized water was not as good. He also washed the lids, brows, and cheek. He stood behind the patient, who was reclining, and operated on the right eye with the right hand, and on the left eye with the left hand. He generally used a two per cent. solution of cocaine in hospital practice, four per cent. in private practice. Put it in twice, and long enough before the operation to dilate the pupil one-half. An important point was to have the middle of the wound brought out under the conjunctiva, so as to have a conjunctival flap. If brought out in the cornea there would be, in a large proportion of cases, a grooved wound, the inner part next the anterior chamber healing first; and the external part becoming covered with epithelium, as it should, there resulted practically an ulcer of the cornea, which might retard the healing for weeks. He had never lacerated the capsule with the knife by going through. Like Dr. Gruening, he did not fear to put the cystotome into the eye after boiling. In two of his cases there was incarceration of the iris. The number of males and females was about equal. The result in one case was only perception of light; in another, perception of fingers, since improved. In 1, V. 22–100; in 3, V. 20–100; in 9, V. 20–70; in 6, V. 20–50; in 8, V. 20–40; in 6, V. 20–30; in 4, V. 20–20; in 2, V. 20–15; in 1, V. 20–10.

Dr. C. S. Bull had nothing but a favorable account to give of simple extraction without iridectomy. The past three years he had done it eighty-one times. In none had there been prolapsus of the iris after the operation. He had already published thirty-six of the cases. In the first thirty he did not get incarceration of the iris once, but in the next six it occurred every time. Out of the eighty-one cases there had been incarceration twenty-one times, in all of which the primary effect upon the pupil was a dislocation upward; in some it subsequently changed in shape. He carefully cleansed the face and eyes before the operation. He used a knife much narrower than the original narrow knife of Graefe. The entire length of the incision was within the cornea. He always endeavored, at the same time, to do capsulotomy. He was quite careful to extract all soft lens matter, however long it might take. If it could not be done by counter pressure, he irrigated the anterior chamber with boric acid solution. He had used Pamard's solution, but not enough to say whether he believed in it as an antiseptic. He used eserine after the operation; and after dressing the eye, if no special cause arose, did not disturb it for three days. The iris, if it became prolapsed, usually reduced itself, but in no case had he had prolapsus subsequent to the operation. He had had eight cases of prolapsus of the vitreous, but in none loss of the eye. He always operated with the patient in the bed to be occupied afterward. He believed posterior synechia was frequent, but the adhesions had never been broad. He used a weak solution of atropia in such cases. He did after operations probably as often as did Dr. Knapp, and was not content even when vision was pretty good. He had operated in two cases of long-continued iridocyclitis with good result, vision in one being 20–30. He could not say that he was nearer deciding on the contra-indications to the simple operation than he was a year ago. The principal advantage of this operation was preservation of the natural appearance of the iris; there was also a good deal better eccentric vision; there was more rapid healing of the wound than after the operation with iridectomy. There was probably better resultant vision in the end, and the possibility of particles of the capsule or lens matter becoming incarcerated in the wound was reduced to the minimum. But the technique was more difficult, the extruding of the lens was more difficult, the iris was more likely to be bruised in the passage of the lens, possible iritis was greater, prolapsus of the iris and vitreous more likely, also incarceration of the iris; and there was greater difficulty of cleansing the pupillary area after the lens was extruded than when iridectomy was performed. The most important contra-indication to the simple operation was a rigid, unyielding iris, which probably could not be determined before operating. He would continue the simple operation.

Dr. Gruening, in correcting a false impression left by his remarks, said that he was not in the habit of extracting the lens with the capsule. He meant only to say that he was in the habit of attempting to do so in hypermature cataracts, and usually succeeded.

Dr. D. B. St. John Roosa mentioned his experience with the different forms of cataract extraction, commencing with his studies under Alt and Von Graefe in 1862. The profession was now coming round again to the simple operation without iridectomy then performed, and Schweiger was even using Beer's knife in the simple extraction. His own experience with cataract extraction now covered over two hundred cases. With regard to extracting the lens in the capsule, he employed this method in every possible case for two years—not by the method of Pagenstecher, or that advocated a hundred years ago, but in attempting to dislocate the lens after section, and causing it to emerge by pressure and counter-pressure. Taking the cases altogether, he thought it was a fairly good operation, but it was more difficult than simple extraction, and for that reason he had, for the present at least, abandoned it, and he now operated by simple extraction, which, in spite of the difficulties which attended it or any operation, was to him the simplest of any he had undertaken. He had no desire as yet to return to Beer's knife. A few days before, taking the advice of Schweiger, he made downward section, and probably would lose the eye, which he believed would not occur had he made upward section.

The flap was on the transparent cornea, healing very well, when on the third day the inverted lower lid, which he so often encountered, pressed directly on the line of the flap and set up a suppurative process which was likely to destroy the eye. The dangers of simple extraction were exactly as Dr. Bull had stated them, but after all it required less manipulation than the Graefe extraction with iridectomy. With cocaine we were able to practise massage in such a way as to get out the cortex as we did not dare do before. As to the advantages of a round pupil, he had always thought they were over-rated. The operation which would save most eyes with useful vision was what the surgeon sought. He did not believe, however, that an ironclad rule could yet be laid down in favor of doing the simple extraction in all cases. He believed there were still cases in which, after making section, it would be decided best to extract with the lens in its capsule, and in other cases do iridectomy.

Dr. Roosa referred to the question of heredity, and said that three weeks ago he operated for removal of

cataract on the fourth member of a family consisting of father, daughter, two aunts, and an uncle, who had cataract. He also had removed a cataract from the father and two sons of another family, and a fourth died before the time set for an operation.

Dr. Roosa thought the mechanical influences interfering with the healing of the flap and causing suppuration were sometimes overlooked, especially rubbing the eyes with the hands.

The Chairman remarked that the danger of catching the iris on the knife was much greater when the narrow one was used than when Beer's knife was employed, and he asked Dr. Roosa why, since we had the old operation of simple extraction without iridectomy back again, not use the old knife?

Dr. Roosa said he had not used the Beer knife for seven or eight years, because it was more difficult to manipulate than the narrow knife.

Dr. Valk read some remarks, and described a method he had employed for overcoming mechanical interference of the iris with exit of the lens. An ideal operation would be to remove the lens in the capsule, without iridectomy. It had occurred to him to overcome the mechanical interference of the iris by drawing it back behind the lens as extraction proceeded, and with this end in view he had had made instruments called iris retractors. They were about the size of ordinary iris forceps, with small, smooth knobs on the ends of the blades, which caught and held the iris backward and downward as the lens passed outward. Then the iris was easily released, and returned to the normal position. He first used it in 1887, and had employed it in all cases since, no matter what the condition of the lens, and with perfect satisfaction. He could not say that it seemed to produce irritation of the iris. He had employed it about twelve times. Dr. Keiser, of Philadelphia, had expressed satisfaction with the method in the few cases in which he had employed it.

Dr. Ferrer, of San Francisco, said he had the past three years done simple extraction without iridectomy in twenty-eight out of over sixty cataract operations. In the twenty-eight cases prolapsus of the iris occurred in none, a fact due possibly to operating only when the patient was in the bed afterward to be occupied constantly six or seven days. He kept the bandage on the wounded eye nine days. He never injected the anterior chamber. His first experience with corrosive sublimate was bad, both eyes being lost. He now used a solution of boracic acid. Out of sixty cases he had lost but one eye from suppuration.

Dr. G. F. Carey had performed nineteen cataract operations, fourteen were modified Graefe's, the remainder simple extractions. The resulting vision had been good, and in two had been 20-20.

SECTION IN OBSTETRICS AND GYNECOLOGY.

Stated Meeting, February 28, 1889.

H. T. Hanks, M.D., in the Chair.

AN ENCEPHALIC FŒTUS.

Dr. Mabbott presented a male fœtus, born at full term, weighing six pounds and a half, normal in development except in the skull and brain. The head sat closely between the shoulders, the eyes seemed to project more than usual, the frontal bone rose a very short distance, when the top of the head became flat and retreated down to the neck posteriorly. Behind, there was an aperture about half an inch in depth and over an inch in its other diameters. At its bottom there seemed to be the rudimentary bones of the base of the skull. Another aperture, probably the foramen magnum of the occipital bone, filled with soft structure believed to be nervous matter, was located near its centre. It seemed possible one or more cervical vertebræ were absent.

The woman was confined January 29th, in an institution, and when the nurse reported that she was about to be confined, she said she expected something unusual, as she had noticed on examination that the fœtus would spring to the touch in a peculiar way. This indicated the convulsive movement from pressure observed in these cases and described by Charcot, and showed that at that time there was life. Dr. Mabbott saw the patient at a later stage, when life in the fœtus had become extinct. He was able at once to recognize the malformation by the touch.

The mother was a Swede, who was still nursing her last child when she became pregnant with this. During lactation she had suffered from alopecia areata, and thought, although there was no other evidence of the fact, that she might have contracted syphilis from her husband. Her husband had suffered from sunstroke, and subsequently from epilepsy. This fact, and that of having been strongly impressed by the sight of a man with a tumor on the face whom she had met in the street, made her fearful that her child would be marked.

Dr. Hanks recalled a case seen by him some years ago, similar to the one described by Dr. Mabbott, except that the brain was more developed. There was absence of a part of the cranial bones as in this one. There was a tumor the size of an egg presenting, which when pressed upon caused the peculiar convulsive movements referred to, and which led to the opinion that it was the brain which was being pressed upon.

Dr. James R. Goffe presented

A DERMOID CYST OF THE OVARY

removed on February 27th from a married woman, who had noticed enlargement of the abdomen over a year. The tumor grew rapidly, and the patient suffered from frequent attacks of peritonitis. On opening the abdomen extensive adhesions were found, the breaking up of which caused considerable hemorrhage. This was controlled by the Paquelin cautery. The tumor contained, in addition to the hair, and also teeth, usually present in a dermoid cyst, a great deal of sebaceous material. It had two compartments, and in one there was a large ball of hair, and a smaller ball in the other. The other ovary was diseased.

Dr. W. Gill Wylie remarked that dermoid cysts, in contradistinction to ordinary cystic disease of the ovaries, were apt to cause much pain, to be of slow development, to occur in women past the menopause, and to undergo suppuration unless operated upon when the pain became severe.

Dr. Mundé believed the arrangement of the hair seen in Dr. Goffe's case, that is, in large balls, was usual. But two years ago he removed a dermoid cyst which contained numerous round bodies, like small marbles, each one containing a single hair. They were floating about in the fluid, which amounted to several quarts. Dr. Welch examined them and said they contained sebaceous matter. He could not state why each one contained a hair projecting from the centre of the ball. There were only four similar cases on record. He had had one case in which the cyst was separated into two compartments, and the hair in one compartment was blond, while that in the other was black.

Dr. Currier inquired of Dr. Wylie how he reconciled his opinion that cysts occurring late in life, especially after the menopause, were likely to be dermoid, with the fact that dermoid cysts were usually considered congenital formations.

Dr. Wylie thought the explanation easy. The germ that developed the dermoid cyst was probably present at birth, but remained latent until the menopause, and at that time, when certain atrophic changes took place, it began to develop. He repeated that in his experience with dermoids, which was large, they were likely to occur in older women, to be associated with pain, to be of slow growth, to have adhesions, and to undergo suppuration.

Dr. Mundé said that, according to his observation, there

were three events in woman's life likely to start the growth of dermoid cysts, namely, puberty, childbirth, and the menopause.

DR. G. T. HARRISON thought that Dr. Wylie's statement with regard to the developmental history of dermoid cysts was true of all tumors of the ovary, namely, that they were most likely to take place after the menopause.

DR. HANKS thought it would hardly be just to come to the conclusion that those who had passed the menopause were more liable to dermoid cysts than others. He had removed three, and had seen six or seven in Dr. Lee's service, and of these only two occurred in women who had passed the menopause. Yet he had no doubt that if the focus were present the menopause might start the development.

DR. WYLIE added that he had not seen enough cases to establish a rule.

THE SURGICAL TREATMENT OF RETROVERSION OF THE UTERUS WITH ADHESIONS, WITH A NEW METHOD OF SHORTENING THE ROUND LIGAMENTS.

DR. W. GILL WYLIE read the paper. Regarding the new method, in his own experience it was not new, as he had employed it for three years, and a modified form a longer time. He excluded from consideration those cases of retroversion with adhesions in which the tubes and ovaries were diseased, for the reason that usually they required removal of the appendages. Yet retroversion with adhesions almost always meant salpingitis, and this fact not having been recognized a few years ago, accounted for the trials of the gynecologist in the treatment of so-called cellulitis, and for the further fact that pessaries did little good. Indeed, often, where retroversion was combined with adhesions (usually salpingitis) the use of the pessary excited fresh attacks of peritonitis, formerly called cellulitis, and did much harm. But there was a certain number of cases where the uterus was held in the retroverted and fixed position by peritoneal adhesions, which did not involve to a serious extent the tubes and ovaries, and it was in that class of cases that he proposed to describe and recommend a simple treatment after the abdomen was opened. Where the adhesions were at all extensive the only possible means of reaching an exact diagnosis was by opening the abdomen, yet he did not recommend laparotomy until other measures to remove the symptoms had proven fruitless. He had held for many years that displacement of the uterus did not constitute disease; that it was the result, rather than the cause, of disease. He had also maintained that adhesions *per se* were not a disease. They were the means by which nature attempted to repair the effects of the disease or shut off extension. The adhesions caused pain only when connected with some diseased organ, or when they interfered with the circulation of some other organ. In the class of cases under consideration endometritis was the disease commonly present, and to cure this it was necessary to secure drainage for the secretions, to stretch the adhesions in order that the uterus might have a certain degree of mobility, and not to interfere with the function of the bowel, or to break them up entirely after opening the abdomen, and then shorten the round ligaments. But forcible means of breaking up the adhesions should never be resorted to before opening the abdomen, as it was then alone that one could feel certain of what he had to deal with. The patient should be kept quiet as long as any fever was present. The uterus could usually be lifted by the finger without the use of much force. Fixation from exudations about the broad ligaments was usually less firm than when the adhesions were attached to the fundus. A pessary was likely to prove intolerable, and in its stead he employed the boro-glyceride pledget of cotton, which, in a few weeks, was likely to bring about involution and render the uterus more movable, and enable him to treat the endometritis by dilatation, drainage, and, if indicated, the use of the curette. If this treatment were continued, and the tubes and ovaries were not diseased, it would usually result in cure. In many cases, however, a cure could not be effected in this way, and on opening the abdomen one would find disease of the tubes and ovaries, necessitating their removal. But in a certain number of cases laparotomy would show that no adhesions had existed, and Alexander's operation might seem indicated. Instead of the Alexander operation for shortening the round ligaments, and thus holding the uterus up, he folded each ligament upon itself (the abdomen being open) in such a way as to shorten it, pass sutures, and cause the folded surfaces lying in close apposition with each other to unite and prevent falling of the womb. He had performed this operation in several cases the past three years, and a similar one as long ago as six years. Its advantages over the Alexander operation were evident. Although he had described it on different occasions, he was led to bring it forward in this special way because it seemed not to have attracted general attention, and also because he had heard that Dr. Baer, of Philadelphia, who was present by his invitation, had lately been doing the operation, supposing it was original with himself.

DR. BAER, of Philadelphia, said that while he had lost much of his belief in the teaching of a few years ago with regard to the pathology and etiology of displacement of the uterus, he was not yet prepared to believe with Dr. Wylie that retroflexion of the uterus was not productive of symptoms. The uterus when turned upside down was not in the position intended by nature, and, therefore, should give rise to symptoms. Certainly the circulation could not take place through it as readily as when it was in the normal position. Even those who expressed a different view showed by their treatment doubt in their expressed belief, for they sought to restore the uterus to a normal condition, and asserted that thereby it would be restored to a normal position. Whether the patient got better because her condition, aside from the displacement, was improved, or because the womb was replaced, might be difficult to say, but he thought both had their influence on the result.

He agreed with what Dr. Wylie had said regarding his method of shortening the round ligaments, and thought it the most scientific, and certainly the most efficient way. Owing to the fact that he believed displacement in itself might give rise to symptoms, he went a little farther, and said he thought laparotomy was sometimes justified for the single purpose of shortening the ligaments and retaining the uterus. In the Alexander operation there was possibility of not finding the ligaments, and after its failure one would be under the necessity of doing laparotomy.

As Dr. Wylie had said, in nine cases out of ten, or not so large a proportion, laparotomy would prove ovarian and tubal disease to be present, necessitating the removal of those organs; but in a few cases one would find that shortening of the round ligaments in the manner described would prove useful, and would take the place of Alexander's operation. It would seem to be as safe as the latter operation, for none of the patients so operated upon had died.

DR. P. F. MUNDÉ had not done Dr. Wylie's operation, but all had probably felt in some cases of retroversion or retroflexion need of something more than the old treatment, of something besides pessaries to retain the womb in position. Yet he had found the pessary of a certain amount of benefit, particularly the Thomas stem pessary with abdominal support. This had even effected a cure of the retroversion in some instances. He was quite in accord with Dr. Wylie regarding the necessity for his operation of shortening the round ligaments in the few cases to which he restricted it. Time, however, would determine whether this, the Alexander, or some other method would prove the best. While he had been a great believer in Alexander's operation, he admitted there were certain elements of doubt in it. It was not indicated at all in the class of cases calling for hysterorrhaphy. The objection to it was not, he thought, that the liga-

ments could not be found, but that in some instances they could not be drawn out. Regarding symptoms produced by backward displacement, he was inclined to agree with Dr. Baer rather than with the author. While he was an advocate of pessaries, it was not for the cure of displacements, nor would they always take the place of one of the operations referred to. Dr. Wylie's operation, if the benefit should prove permanent, possessed certain marked advantages over hysterorrhaphy. The latter fixed the uterus to the abdominal wall, and was also liable to be followed by intestinal strangulation.

Dr. George T. Harrison said that retroflexion was a pathological state, and that no woman could have good health for any length of time who had a retroflexed uterus. Every case required treatment. It was claimed that Alexander's operation restored the uterus to the normal position, but this was not so; it converted a retroflexion into an anteflexion, and when it was thus fixed forward there was interference with the normal excursions of the organ, which was objectionable. This was particularly true of hysterorrhaphy. He had little doubt that a good many of the women so operated upon would have bladder trouble, and perhaps trouble also if pregnancy occurred. Therefore it was a matter of congratulation that there was a method at hand by which the physician could cope with almost all cases of retroflexion complicated by perimetric adhesions, that was massage. He did not refer to Brandt's method, for he knew little about it, but that which had proved successful in his hands for years. In addition, pessaries were employed, giving the relaxed muscles (ligaments) an opportunity to regain their contractility.

Dr. A. F. Currier thought that in some cases displacement backward might exist for even months and not be attended by symptoms, while in others engorgement ensued, necessitating treatment. A third class of cases was that where displacement had existed for a long time, and caused atrophic changes in the uterus, a condition which was incurable. In backward displacement the broad ligaments were folded upon themselves, their surfaces became adherent, thus there resulted four layers of peritoneum adherent to each other, and to overcome such adhesions great caution should be exercised. He mentioned a case which he treated by Schultz's method with unsatisfactory results. Regarding the use of pessaries, he believed they would cure some cases, more particularly in unmarried women. Alexander's operation, Wylie's, or hysterorrhaphy, had their indications, but should never be performed except by a surgeon of some experience.

Dr. Hanks said, regarding operative procedures for replacing and retaining the uterus, that he would as soon have laparotomy, followed by Wylie's operation, or hysterorrhaphy, performed upon those dearest to him as Alexander's operation, so far as risk was concerned, while the curative results would be more certain. He knew of two cases where, after fixation of the uterus to the abdomen, pregnancy progressed without hinderance. Pessaries would cure in some cases, and he thought that when the uterus remained in position a year without support, and then again became retroverted, it should be considered a recurrence, just as a second attack of pneumonia some time after the first was a recurrence, the first attack having been cured.

Dr. Wylie, in closing the discussion, said he did not bring his operation forward for use where the pessary combined with other treatment would cure the case. He did not recommend it for the cure of diseases of the uterus, but the endometritis could be treated better with the organ in corrected position. This method and the pessary only removed one of the incidents and not the disease. So far as massage treatment was concerned, he employed this in the preparatory treatment, but it was not sufficient in all cases. Dr. Currier had spoken of the broad ligament being folded upon itself and adherent. He thought that in such cases laparotomy would prove the true condition to be one of salpingitis. He believed the question of mobility in the uterus was more important than that of position. Raising the organ made it more mobile. He had seen no trouble with the bladder following his operation.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE TREATMENT OF CONFIRMED CATHETER-LIFE BY THE FORMATION OF A PERMANENT PERINEAL FISTULA—A REMARKABLE CASE OF FRACTURE OF THE SKULL, WITH CEREBRAL ABSCESS—A PROPOSED DENTAL SECTION AT THE ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION—A NEW DEPARTURE AT THE MIDDLESEX HOSPITAL — PROPOSED COMPULSORY NOTIFICATION OF INFECTIOUS DISEASES.

London, March 9, 1889.

A noticeable feature of our medical meetings is their tendency to assume more of a cosmopolitan character. It is now by no means infrequent for a London physician or surgeon to bring a communication before a provincial medical society, and, conversely, it is becoming increasingly common to meet with practitioners from the provinces, or even more distant parts, at our metropolitan gatherings. Thus, on Monday evening last, at the Medical Society of London, the first paper was read by Mr. Walter Whitehead, of Manchester, whose name is probably familiar to your readers in connection with the method of removing the tongue which is named after him. On the present occasion, however, a different branch of surgery occupied Mr. Whitehead's attention, the subject chosen for his paper being "The Treatment of Confirmed Catheter-life." The formation of a permanent perineal opening was advocated. The author said he had found this plan to be very effectual; he also believed it to be novel as applied to the advanced stages of prostatic obstruction. The operation performed did not differ materially from that of an ordinary median lithotomy. The originality commenced with the after-treatment. An India-rubber tube was passed through the opening made into the membranous urethra and allowed to remain until a sufficient time had elapsed for the fistulous communication with the bladder to become cicatrized. The tube was then no longer worn continuously, but the urine was withdrawn through the fistula at intervals by means of a catheter.

When cystitis coexisted with enlarged prostate the bladder should always be irrigated before withdrawing the catheter. By this method of treatment the bladder could at pleasure be completely relieved of its contents, a permanent channel was provided through which a perfect could be substituted for an imperfect method of washing out the bladder, and six inches of the most sensitive part of the urethra escaped the irritation produced by the passing of a catheter in the ordinary way. By allowing the opening to remain permanently patent, relapses were avoided. The author further claimed that by this method all the inconveniences attending enlarged prostate were permanently arrested without incurring the risks of a really serious operation.

Sir William MacCormac said the direct approach to the bladder would certainly relieve many of the distressing symptoms, but asked whether such patients were not still liable to attacks of difficulty of micturition in consequence of obstruction by the middle lobe of the prostate. Mr. Buckstone Browne spoke in favor of the suprapubic operation. He said an operation similar to that described had been performed for years, and he questioned the assertion that a permanent fistula was seldom or never met with unless expressly provided for. In his experience fistulæ commonly resulted from the central incision, and it was difficult to get them to heal. He had also seen septicæmia, hemorrhage, and even death follow the perineal

incision. Mr. Buckstone Browne's vigorous attack was followed by a few words from Mr. Bernard Pitts, who observed that the cases were so disappointing that all suggestions as to treatment were welcome. He had performed perineal urethrotomy in two cases of enlarged prostate, but both patients died in a few weeks from exhaustion. He did not think, though, that the dangers alluded to by the previous speakers were to be apprehended if the incision were kept in the middle line. The suprapubic operation had the advantage that it enabled a more radical procedure to be adopted if necessary, and it was certainly the best in cases of vesical tumor. Mr. Whitehead then replied, and said the prostate was a mysterious body, symptoms being sometimes present where it was normal or even smaller than usual. He had done the perineal operation two or three hundred times, and only once had he met with an intractable fistula as the result. With the suprapubic operation an instrument had to be worn in the opening, and simply served as an overflow pipe which could not readily be controlled; the perineal opening required no instrument to be constantly worn, and patients had no difficulty in holding their urine for four or five hours, while it could be drawn off with a short tube when necessary.

Mr. J. H. Morgan, surgeon to Charing Cross Hospital, then related a somewhat unusual case of compound comminuted fracture of the skull. A boy, nine years of age, sustained an injury to his head causing a scalp-wound at the apex of the right parietal region. A small portion of bone was exposed, but no fissure could be seen. There were symptoms of severe concussion, and on the fourth day a convulsion occurred, followed by paralysis of the right arm and leg. The scalp was then exposed and a piece of bone was found depressed, situated two inches from the middle line, vertically above the right ear, and at a distance of an inch and a half from the original scalp-wound. Thick pus exuded through the torn dura mater from an abscess-cavity in the region of the right ascending parietal convolution. The bone was elevated and the abscess emptied; the unhealthy granulations lining its cavity were removed by scraping. Several convulsions occurred in the course of the next few days, in which the face, abdomen, and right extremities were affected; but these diminished in severity, and ceased altogether by the fourth day. Hernia cerebri seemed to be threatened at one time, but the granulations shrank to a level with the scalp, under the free use of iodoform. The paralysis gradually disappeared, and there was now no sign of weakness in the arm or leg, the boy being perfectly well.

It is proposed to have a Dental Section at the Annual Meeting of the British Medical Association. The success which could be achieved by such a section is, however, somewhat problematical. Only a small minority of dental practitioners possess medical as well as dental qualifications, and the present constitution of the British Medical Association does not allow of the election, as members, of others than those qualified to practise in accordance with the medical acts. I am afraid, therefore, that the attendance in the proposed section would be somewhat limited.

A new departure is about to be taken at the Middlesex Hospital. The committee have determined to establish an out-patient department for diseases of children, and an additional assistant-physician is to be appointed to take charge of it.

It is stated that the Government are about to bring forward a bill to render the notification of infectious diseases to the authorities compulsory on the part of the medical attendant. Such a system is at present only in force in a few localities, where it has been brought into operation under local acts of Parliament.

THE MILLS OF THE COLLEGES grind swiftly but exceedingly coarse.

ON THE USES OF ELECTRICITY IN MEDICINE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: That a reaction from the old-time credulity of the profession in regard to electro-therapeutics is taking place, the discussion at the last meeting of the New York Academy of Medicine shows.

The enthusiasm which formerly swayed the multitude was imported from France and Germany, and now the ebb of the tide which lays bare the foundation-stones of electro-therapeutics, one of the gentlemen discussing the subject the other night would have us believe, has started from England.

Dr. Starr credited Gowers with being the first to express in print, in his very recent book on nervous diseases, ultra-conservative views on electro-therapeutics. As a firm believer in American common-sense, I protest at any such statement. That some of us eagerly swallowed the Continental bait ten or twelve years ago, I must admit, but that it has taken us twelve years to find out we were sold, I deny. Some of us at once set ourselves to personally and experimentally prove the correctness of the stupendous claims made by Continental electro-therapeutists, with the prompt result of finding most of them a lot of bubbles.

In the spring of 1884 I collected in book form some lectures on electro-therapeutics,[1] which I had been delivering for three years, with other lectures on therapeutics in the Woman's Medical College of the New York Infirmary. A part of its preface runs thus: "This little book is presented to the medical public chiefly as a protest against the mysticism and charlatanry which have ever hung around the literature and practice of electro-therapeutics. . . . Its (electricity) showiness, its instantaneous and startling physiological effects, and its name, popularly synonymous with life, have long made it, and will long continue to make it, a fashionable remedy, a cure-all for imaginary diseases, a popular placebo, a gold mine for charlatans and symptom-treating physicians, who let their patients make the diagnosis and suggest the treatment.

"Never does the question, 'Was my patient cured, or did he get well?' arise so often as in the practice of electro-therapeutics; other remedies are so often simultaneously employed, the treatment, as a general thing, extends over so many days or months, and so much allowance must always be made for the effect of expectant attention."

On p. 62, in commencing the therapeutic part of the book, will be found the following words: "By far the most brilliant curative results brought about by electricity depend wholly on its power to excite muscular contraction."

Where treating of spinal diseases there will be found, on p. 71, these words: " . . . Electricity, applied externally, has very slight action on the healthy cord, and hardly any undeniable therapeutic effect on it when diseased." Again, concerning cerebral diseases, p. 76: "Electricity, as ordinarily applied to the head, is devoid of any curative power over tangible cerebral lesions."

"Contracture of cerebral origin is not very amenable to electrical treatment. . . . Relief, if any follows, is slight and delayed" (p. 80).

As to ocular paralyses, p. 81: "So frequently is this treatment combined with medication, and so slow, as a general thing, is improvement, that the real utility of the procedure is questionable."

Concerning spasmodic affections, p. 83: "Tonic spasms, depending on a cerebral or spinal lesion, are not very amenable to direct electrical treatment. . . . Attempts to reach the seat of the lesion by galvanizing the head and back yield no better curative results. A speedy and decided relief of a contracture of supposed spinal or cerebral origin, would lead me to doubt the correctness of the diagnosis."

Concerning the temporary relief of clonic spasms, p. 84: "A prolongation or repetition of this application,

[1] The Student's Manual of Electro-therapeutics. New York: G. P. Putnam's Sons.

however, is attended by no curative results." Concerning pain, p. 86: "Pains of a cerebral origin, or from disease of the spinal cord (as in sclerosis of the posterior columns) are not amenable to electrical treatment. When caused by acute neuritis also, other remedies are much more indicated. . . . Relief following electrical applications, in pain of obscure causation, often comes from expectant attention, as is proved by the magical effects which often follow the application of electrodes entirely devoid of electricity."

Concerning electrolysis and galvano-cauterization, p. 90: "They should supplant cleaner and more surgical procedures only when the site of the operation is too inaccessible for concise dissection or hæmostasis."

Though not advanced by a European, it would seem as if these ideas were conservative enough, particularly as they were taught and published at a time when everybody else was curing (?) with electricity locomotor ataxia, progressive muscular atrophy, pseudo-hypertrophic paralysis, glosso-pharyngeal paralysis, tetanus, torticollis, club-foot, aneurism, asthma, exophthalmic goitre, impotence, urethral stricture, epilepsy, melancholia, strabismus, and cataract. One thing which has bolstered up the reputation of electricity as a curative agent more than anything else, is the extraordinary and utterly fallacious way in which it gets all the credit for results often due to other treatment employed at the same time. Let us cite a few examples.

Says a recent writer[1] on medical electricity: "It is necessary in skin diseases to enforce the most rigid attention to diet, cleanliness, and bowel regularity, before doing anything else." Pretty good treatment for acne without electricity. Another[2] has cured three cases of epilepsy by a special application of the constant current to the brain, and *the administration of small doses of the bromide of sodium.* (Italics mine.) Another author[3] reports several cases of epilepsy cured (?) by the combined use of the *bromides* and *electricity.* (Italics mine.)

In a case of aortic regurgitation an observer[4] used "general faradization, daily applications, using extreme care over the cardiac region, as any sharpness of current was followed by faintness. *The only medicine employed was lily of the valley tincture.* . . . " (Italics mine.) Very numerous examples of such erroneous deductions could be cited. Another source of error is a failure to properly estimate the proportion of recoveries that take place spontaneously during a prolonged electrical treatment.

An author, speaking of the treatment of acne, says:[5] ". . . It is scarcely worth while to begin a case without some sort of assurance that treatment will be continued at least a year, steadily and faithfully." What changes will mere attention to hygienic details bring about in that space of time! Again, in a case of herpes præputialis the same author says:[6] "Applications were made daily, and after *twenty* the patient was discharged, cured." (Italics mine.)

The same author, with reference to heart disease, says:[7] "I have found daily applications essential to any kind of success, and at least three months' treatment necessary for relief."

The preposterous claims of cure made by some men can be charged to their dense ignorance, which is mirrored in their writings. As an example I refer the reader to the following case[8]: "Case III.—G. F. S——, a physician, in excellent general health, consulted me for a ptosis of the right eyelid. . . . He was also slightly myopic. The levator muscle was regularly faradized for two weeks, general applications of the same current to the ball being made by the electric eye-cup for the same length of time. He was then obliged to stop treatment by absence from the city, but the ptosis had very much improved, and *the myopia also.*" (Italics mine.) As though the shape of the eyeball could be permanently changed by faradism! The same author claims to cure cataract, while among other diseases which he treats with electricity are capillary bronchitis, acute phthisis, pneumonia, heart disease, angina pectoris, intercostal neuralgia, pleurodynia, hiccough, chronic gastritis, intestinal dyspepsia, rectal stricture, jaundice, and peritonitis. Should one care to study the humorous side of a very serious subject, in the writings of electro-therapeutists, he would find a very fertile field.

To exemplify a phase of the subject scrupulously avoided by writers and disputants, the following case[1] of asthma will furnish a text: "Case I.—S. T——, aged sixty-four, retired merchant, of hereditary asthmatic history, etc. . . . Treatment was commenced on the 17th of April, 1880, and continued for two months." (The treatment consisted in what the author calls "cerebral alternated with pneumogastric treatment.") "The paroxysms grew shorter and less severe, and the patient became able to take some interest in life once more. At this time, however, unfortunately, he became embarrassed in circumstances and was obliged to suspend (treatment). . . ."

How pregnant with meaning is this last sentence! Can it be that so potent an agent is good for the rich, but bad for the poor?

I will here make a statement which I have no fear anyone will honestly contradict: That ninety per cent. of electrical applications are made either through ignorance or avarice; the latter motive being by far the most common. There is no other way—unless it be the hypodermatic treatment of syphilis—whereby a patient can be induced to come to a doctor's office so often, so regularly, and for so long a time as to undergo a thorough "course of electricity." This knavery and humbuggery is rampant all over our land, and in any other profession or business than medicine would be branded as it deserves.

The indications for the use of electricity are just as plain and concise as are those for opium, aloes, or digitalis, and at some future time I should be pleased to present them, but the limits of a letter are already overstepped. Let me add to my readers these words of advice: Don't use electricity without knowing *why* you use it; don't use electricity as a placebo, it takes too much time and is too expensive; and last, but by no means least, don't use electricity simply to make money; it is unprofessional, and brings medicine into disrepute.

R. W. AMIDON, M.D.

NEW YORK.

A GOOD BREAD FOR DIABETICS is made from the gluten from the starch factories ground to a fine flour. In the ordinary method of manufacture the gluten is fermented out and lost, but lately efforts have been made to separate it out by machinery for sizing. The bread is made as follows:

One cup gluten flour; one cup best bran, previously scalded; one teaspoonful of baking powder; salt to taste; two eggs; one cup of milk or water.

To be mixed with a *spoon.* If the hands are used the result will be even more disastrous than in the making of ordinary bread. This bread is healthy, palatable, nutritious, and contains but 4.57 per cent. of starch, equal to 5.08 per cent. of sugar. The analyses were made by Dr. Charles Harrington.

I presume that this bread is practically the same as that described by Waltering (*Allgem. med. Central Zeitung*, August 4, 1888), whose article by accident did not come to hand till recently.—JOHN A. JEFFRIES, *Boston Medical and Surgical Journal.*

New Instruments.

A NEW PALATE-RETRACTOR.

By ALFRED HINDE, M.D.,

CHICAGO, ILL.

During the last five years I have used a palate-retractor which for cheapness, simplicity, ease with which it is kept clean, and, above all, efficiency, excels any like instrument with which I am acquainted.

In cases where posterior rhinoscopy is impossible, from insufficient space between the velum and the posterior pharyngeal wall, and also in cases where the post-nasal space needs cleansing previous to local application, and again during the latter manipulation, a retractor is found to be a necessary instrument. The perfected instrument,

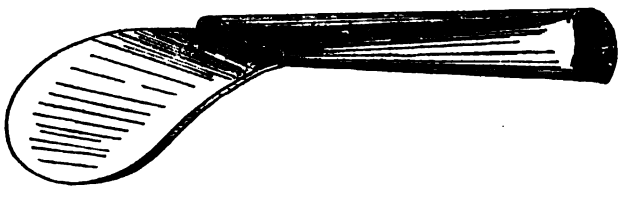
of which the above figure is a representation, is made in one piece, of steel, and nickel-plated. It consists of a handle, three inches long, with a shaft, five inches in length, terminating in an equilateral triangle, each side of which is half an inch in length. This triangular portion is bent upon the shaft at an angle of 75° to 80°. The first instrument I made out of an aluminum probe, in a wooden handle, but the too great flexibility of the metal impaired its usefulness.

A TONGUE-DEPRESSOR AND INSUFFLATOR.

By J. D. OSBORNE, M.D.,

NEWARK, N. J.

In writing a paper on "Diphtheria," read recently before the Practitioners' Club of Newark, N. J., I was led, both by my own experience and that of others, strongly to advocate the use of sulphur, both locally and constitutionally—locally, as prophylactic, and in the early stages and throughout the course of the disease, either in the form of sulphurous acid or in powder; and constitutionally, as sulphide of calcium, sulphurous acid, sulphite or bisulphite of soda, or the washed sulphur itself. Experimenting as to the best means of applying the powder to the throat, I was



led to construct this little instrument. It is a tongue-depressor and retractor and insufflator combined, and consists of a tube, eight or ten inches long, having attached to it an inverted spoon-shaped depressor, bent or folded somewhat on itself. The end of the tube covering the spoon is flattened and depressed in the centre, for the purpose of scattering the powder laterally on the tonsils as well as directly in front on the fauces. I first designed it for family use, and had it constructed of cheap material, nickel-plated, so that it can be sold by the druggists for twenty-five cents, when ordered by the physician. But I found it had a more extended possible use than I antici pated. It can be made better and of more expensive material, if demanded, for the use of the physician himself, both in his office and at the bedside. The bent spoon retracts the tongue, while its shape makes it glide over it with much less disturbance than the ordinary tongue-depressors; and being highly polished on the upper surface, lights up the upper part of the throat and posterior nares. It can be used by blowing through it with the mouth, or by any insufflator. The rectal tube of the universal Davidson's syringe fits sufficiently accurately into it, while its rubber tubing can be fitted over it, using a single pressure of the bulb to blow the powder. Any atomizer with projecting point will throw spray through it.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 23, 1889:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	8	0
Scarlet fever	394	50
Cerebro-spinal meningitis	1	1
Measles	161	15
Diphtheria	176	35
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

The Question of Puncture in Hydrocephalus.—At a meeting of the *Berliner Medicinische Gesellschaft*. Dr. Ehrmann presented a case of hydrocephalus, and raised the question whether puncture is beneficial or harmful. Professor Henoch, the specialist in children's diseases of the Charité, replied that he often—five and even six times in one and the same case—performed the operation of puncture and subsequent compression, and that he had never seen any injurious results proceeding from it. But at the same time he never saw any benefits from it.—*The Medical and Surgical Reporter.*

Fracture of the Symphysis Pubis during Labor.—In the *Annales de Gynécologie* for October, 1888, Dr. Faux relates the case of a woman, twenty-five years of age, who had been in labor over forty hours at the time he saw her. The forceps were applied and delivery effected. When the head reached the perineum a cracking noise was heard, and this was repeated as the head was born. On the following day it was discovered that a separation of the pubic bones had taken place at the symphysis.

REMOVAL OF A TUBERCULAR TUMOR OF THE LARYNX BY LARYNGO-PHARYNGOTOMY, WITH DEMONSTRATION OF CASES.[1]

BY ARPAD G. GERSTER, M.D.,

NEW YORK.

THE object of this brief communication is twofold. *First*, I wish to contribute a rare instance of the successful removal from the larynx of a tubercular new growth, and, *secondly*, to bring to the notice of the profession a modification of the usual procedure, which tends to lessen the dangers of the operation itself, and diminishes the risks that arise during the time immediately following the operation.

Tuberculosis of the larynx is as well known as it is intractable. The ordinary appearances marked by diffuseness of the process need not be dwelt upon at present, as the object of this paper is rather to deal with one of the rarer forms of laryngeal tuberculosis, namely, that characterized by the formation of well-defined solitary or multiple tumors. Hennig, of Königsberg, says, in a paper published last year (1888), in No. 28 of the *Berliner Klinische Wochenschrift*, that, aside from his own case therein reported, only six additional instances of tubercular tumor of the larynx could be found laid down in medical literature.

Undoubtedly this form of the affection cannot be as rare as the paucity of reported cases would seem to indicate; yet it is rare enough to deserve the distinction of careful recording whenever met with.

Before entering upon the subject-matter of this paper, permit me to touch upon considerations that bear upon the question before us.

The appearance of strictly local tuberculosis is extremely rare, and its acceptance must be limited to those cases that owe their origin to direct inoculation. Most instances of so-called surgical tuberculosis are complicated, that is, mainly secondary to recent or old deposits in the bronchial glands or the lungs themselves. Extending experience in this field has taught me to look for and to find almost invariably signs of recent or old chronic trouble about the respiratory tract in patients suffering from some form of local tuberculosis.

In former days the presence of a pulmonary lesion accompanying a strumous local affection was accepted as a counter-indication to incisive operative relief. Within my own recollection cases are not few where surgeons declined to perform amputation for the removal of "carious joints," as they were called in those days, or refused to cut for fistula in ano on account of the presence of an active pulmonary process.

Fortunately, our views regarding the operative treatment of tuberculous affections have undergone a radical change for the better. We know that as long as the deposits are few and not too extensive, or complicated by acute and rapidly destructive suppuration, complete excision of one or more of the accessible foci will lead not only to local cure, but the elimination of these sources of pain and tissue-waste will also improve the general condition and power of resistance of the individual to such an extent as to be followed by self-limitation and more or less prolonged latency of the surgically inaccessible pulmonary affection. I herewith present to you, as an illustration of this statement, a patient who came under my care about a year ago in a state of great emaciation due to pulmonary trouble, complicated by tuberculosis of the left testicle and of the right knee-joint, both of these local conditions being far gone, and accompanied by the formation of abscesses. Castration and a rather extensive excision of the knee-joint, rendered very difficult by the presence of several large intermuscular abscesses, nevertheless resulted in cure of the local complaints, and also led to a limitation of the hectic, the profuse expectoration, the stitches in the side, and the general deterioration due to both the maladies and confinement. The patient, who was a hopeless invalid, is rejuvenated, and is working again at his profession as hard as ever.

Laryngeal tuberculosis, we must confess, rarely offers as favorable chances for curative interference as the instance here demonstrated. The closeness to the larynx of the lungs, the place from which, ever and anon, new infective material is brought up, to deluge the parts involved in the act of expectoration, renders multiple infection very common, and hence the most ordinary form of laryngeal tuberculosis is characterized by diffusiveness of the inflammatory changes due to the presence of the bacillus.

Nevertheless, we are gratified to be able to record brilliant achievements in the endolaryngeal therapy of tuberculosis, rendered much easier and more successful by the employment of cocaine and iodoform.

To return to our parallel, we now wish to state that occasionally laryngeal tuberculosis assumes a circumscribed character, causing here, as often elsewhere, the appearance of a tolerably well-defined tumor, and that by the timely extirpation of the swelling not only elimination of the destroying dyspnœa and dysphagia can be achieved, but that the general improvement of the vital conditions may occasionally be followed by an improvement of the causal, that is, the pulmonary trouble.

The history which forms the nucleus of this paper is as follows:

P. L——, compositor, a Russian Hebrew, aged twenty-nine, was admitted to Mount Sinai Hospital, October 14, 1888. He had been suffering from prolonged pulmonary catarrh since a number of years. In 1886 he swallowed a fish-bone, and felt some pain in the throat for a few days following. In June, 1888, he began to have pain in deglutition of solids; later on the swallowing of liquids was also causative of dysphagia, and recently the intense pain became complicated by increasing dyspnœa, hoarseness, and a racking cough. Has had some endolaryngeal treatment, which, however, failed to give him relief. On admission his general condition was fair, though anæmia was marked. Apical condensations and the usual symptoms of a chronic pulmonary catarrh were noted. Temperature, 99° F.; urine normal; respiration noisy, the inspiration being much prolonged. Laryngoscopic examination revealed a tumor of the size and shape of an unshelled almond, occupying the site of the left arytenoid cartilage and ventricular band, and overlapping the entrance to the larynx to such an extent as to preclude the examination of its interior. The surface of the tumor was smooth, pink in color, and seemed to be covered by somewhat hyperæmic, but otherwise normal, mucous membrane.

[1] Read before the Laryngological Section of the New York Academy of Medicine, February 26, 1889.

yet so perfect but that some motion, though very slight, could be obtained. In four months the union, though fibrous, was so firm that motion could not be detected (Fig. 2).

He had now acquired an elasticity in his movements which so concealed the imperfection of the leg due to stiffening of the knee, that it was difficult to detect his infirmity.

About this time I again called Dr. Wood's attention to him as a boy who had an affection of one leg which impaired his gait, and asked his advice as to the proper procedure to remedy the defect. He did not recognize the lad as the patient whom he had formerly seen, and after directing him first to walk and then to run, declared that he saw nothing wrong in his movements.

I have now operated in a number of cases, and always with results similar to those already detailed. The cases selected are those in which the atrophied limb is only slightly shorter than the well limb. Although the anchylosis has been firm when only bone has been excised, yet the union has been very slow. In three cases I have excised only the femur, but in the others I excised both bones. The latter united more promptly, though there was more shortening.

MEDICAL CASES IN THE COURTS.

By HENRY A. RILEY, Esq.,

NEW YORK.

Dr. Isaac Lewis Peet recently furnished to the *Columbia Law Times* an article on "The Legal Relations of Deaf-Mutes to the Hearing Community," and cites a case in New Mexico, occurring in 1883, where three white men were tried and convicted of the murder of three Chinamen. The only testimony connecting the defendants with the deed was that of a deaf-mute between eight and nine years of age. He had never been to school, but had learned to communicate with his mother by signs. According to the mother's testimony, on the same evening that the killing took place, the child came into the bar-room of the public house kept by his parents, in a state of great excitement. He drew his finger across his throat, took a stick and pounded with it, and raised it as if in the act of shooting, and went through the motion of falling. The mother appealed to a soldier who happened to be present, and asked him what the child meant. The soldier, thinking he referred to a difficulty which had lately occurred between two soldiers at the fort in the vicinity, pointed to himself, but the little boy pushed him aside, and pointed to Duran, one of the defendants, and putting his hand to the back of his head, represented the braiding of three queues.

The next morning the deed was discovered, and the third day the boy was placed on a horse to lead a party of investigators. Keeping considerably in advance, he struck the trail of the horses which the murderers had ridden, and followed it on a circuitous and out-of-the-way route, off from any road, to the very house where the Chinamen had been killed, and by signs and actions expressed astonishment at not finding the bodies. He again went through the motions of killing the three queue-wearers, and described the murderers by drawing his finger around his throat, by twisting his nose, and by dotting his face with his fingers. Of the defendants in court one had a clearly defined mark around his throat, another had a broken-down nose, and the other was decidedly pock-marked. Before the court he drew a plan of the house and grounds, and objects in the immediate vicinity, the roads to and from the place, and its location to Fort Bayard. On this plot he also marked out the position of each of the defendants while in the act of killing the Chinamen, and also his own position holding the horses. The way in which he happened to be an eye-witness, and indeed the only eye-witness of the deed, was that he was a great pet with the frequenters of his parents' tavern, and among others of the lawless men who were identified by him. He was accustomed to ride with them on their expeditions, and was greatly amused and interested by their ordinary exploits. But accompanying them on this occasion, his innocent soul revolted in horror at the cruel deed which they had not hesitated to let him see, because they were certain that no accusation could be made against them by a dumb witness.

The child's testimony was admitted by the trial judge, who said: "This little boy has no education, yet I am inclined to believe that, notwithstanding the fact that the mother is unable to communicate to him any questions to test his knowledge of an accountability to a Supreme Being, yet, as a psychological fact growing out of his mental condition, he would be incapable of communicating any events except such as he had seen. He would be incapable of manufacturing or inventing a falsehood as to the material facts, because he could have no idea of the facts unless he had seen them. In my opinion this would be a better test of the truth, or at least as good a test of the truth, as would be the belief of a man of mature age and clear understanding in his accountability to the Supreme Being."

The boy's testimony was therefore accepted, but on appeal this decision was reversed, and the court said: "A deaf and dumb child who has never been educated in an institute for deaf-mutes, who cannot be made to understand anything of the nature of an oath, and who can do nothing more than give an account of what he saw, without affording any means of examination or cross-examination, is not a competent witness, especially in a capital case."

This reasoning is far from satisfactory, and although the occasion was a strange one, and the testimony of a very novel character, yet some ground should have been found or made for letting it in. As one of the dissenting judges said: "The books nowhere furnish a precedent like this. If the law of evidence in no way opens the door for testimony of this kind, then all I have to say is that the law in this respect is certainly at fault, and the sooner it is changed, either by judicial precedent or by legislation, the better."

Texas has not been generally regarded as the fountain-head of legal wisdom, and not long since the Supreme Court of the State attempted to reverse the ruling of the United States Supreme Court; but this gallant effort of a lost cause went down in the last ditch, and the learned judges of the Washington court were left possessors of the field. It must not be supposed, however, that the Texas judges always proclaim bad law, and they certainly have some humorous cases on their calendar. In a recent case in that State of magnificent distances, suit was brought for damages, because a person had been unnecessarily obliged to ride some two hundred miles on a buck-board. The action was against the Western Union Telegraph Company, for not delivering a message in which the sender asked his father to meet him with a carriage at a town called Pena. On his arrival at this place no father or carriage appeared, and the traveller was obliged to travel a long and circuitous route to reach his home at Edinburgh.

On the way he had time for reflection and thought, and he became more and more convinced that his father must be dead, or he would have sent a carriage. This idea so affected his health and produced so much mental anguish that, when he arrived home and found that the telegram had never been delivered, he determined that the Western Union Telegraph Company should pay him a round sum as a balm to his wounded feelings.

The court did not, however, take this view of the matter, and refused to balance lacerated feelings by cold cash. In refusing the plaintiff's demand, it took occasion to say: "Had it been a fact that no other conveyance could be procured from Pena to Edinburgh except such as those upon which plaintiff took passage, it could not have been anticipated that in the usual course of such a journey

plaintiff's posterior could become bruised or lacerated to such an extent as to cause physical pain. . . . In this case it seems that the plaintiff's mental anguish was not the result of any real or adequate cause. It does not appear that the father was dead, or in such a condition as demanded the personal presence or attention of his son. On the contrary, the sorrows of the plaintiff were imaginary, and were caused by the failure on the part of the father to send the carriage to Pena, which the affectionate son attributed to the fact that the father was dead or too dangerously ill to attend to ordinary business, when, in truth, the failure was due solely to the fact that no request to send forward the carriage had been received.

"The deduction of the son was not logical, or, at all events, the occurrence might have been well accounted for on other hypotheses than the disability of the father. If grief or sorrow, produced by things unreal, mere figments of the brain, are held to give a cause of action for a breach of contract or a tort, an individual of a sombre, gloomy imagination would be entitled to large damages on account of mental suffering, while others of a buoyant fancy, for the same breach of duty, would not be entitled to anything; and damages, instead of being measured by the rules of law applied to the rule of facts, would largely depend upon the fertility of the imagination of the suitor." The court, therefore, in an unfeeling way, declined to aid the plaintiff in the attempt to wring unwilling cash from the treasury of the Western Union Telegraph Company.

In another case in the same court the same telegraph company was also defendant in a suit to recover damages for wounded feelings. In this case a husband sent for a physician by telegram, asking him to attend his wife in her confinement. The messenger went twice to the office of the physician to deliver the message, but not finding him, made no further effort to secure his services. In the meantime the plaintiff's wife gave birth to a still-born child. In a suit to recover damages, the mental suffering of the plaintiff was alleged as a ground for recovering a verdict; but in this case, as in the former, the court held that such harm was too indefinite and remote. It said: "We do not think the death of the child before birth, and the grief or sorrow occasioned thereby, can be an element of damages in this character of suit. If it is made to appear from the testimony that Mrs. C—— suffered more physical pain, mental anxiety, and alarm on account of her own condition than she would have done if Dr. Keating had been in attendance upon her, and the failure to secure his services is shown to be due to the want of proper care on the part of defendant's servants, whose duty it was to deliver the message, a fair and reasonable compensation should be allowed for such increased pain and mental suffering; but the death of the child, the bereavement of the parents, and their grief for its loss, cannot be considered as an element of damages. Such damages are too remote."

The right to recover for medical services, to be rendered in the future, is an important one, where a person, and particularly a minor, is injured through the carelessness of other persons. This question came up in the case of a child who was injured by a street-car belonging to the Brooklyn City Railroad Company. The action was brought by the parent for loss of service, resulting from the accident to the child, and the court submitted to the jury the claim also for future medical services, and a verdict was rendered including this. The only ground of action conceded by the law in an action by the parent is the loss of service suffered by him in consequence of the disability of the child; pain and mental suffering are not strictly grounds upon which the parent can recover, though in actual fact juries generally are swayed by such considerations. An action by the child himself would properly bring up such elements of damage.

In the case just cited of the Brooklyn City Railroad, the child had in fact brought suit and recovered, and now the parent sues again for loss of personal service and the probable cost of future medical services. As the trial judge allowed the last element to be considered, the case was reversed by the Court of Appeals. The ground of the decision is thus stated: "If recoverable by the parent, it must be on the ground of the obligation to maintain the child. But not only may the parent die or the child die, thereby rendering the surgical expenses unnecessary, but the parent may become wholly unable to pay for the services required, or the child may be treated in a hospital or at public expense, as was the fact in this instance, when the child's leg was amputated."

When Mrs. D—— was convicted in this State, about two years ago, there was a great deal of undeserved sympathy expressed for her, and a strenuous but unsuccessful endeavor was made to secure a commutation of the sentence.

There is now the same effort being made in Philadelphia to secure a commutation of the death sentence for another female poisoner. The woman was convicted of murdering her daughter, aged nine years, and her husband and an infant son had been put out of the way previously. All of these hideous crimes were committed for the sake of the insurance on their lives, amounting only to a few hundred dollars. The petition which has been presented to the Pennsylvania Board of Pardons, says that "the imposition of the death penalty upon a woman is abhorrent and repulsive to humanity, and particularly shocking to the women of Philadelphia."

It is hardly desirable for this effort to succeed, it would very likely be mistaken mercy. A woman who will murder a husband and two children merely to obtain a few hundred dollars of insurance, has too much of the fiend in her disposition ever to be a safe member of society.

If it were not a sad fact that few criminals serve out a life sentence, but secure a pardon after a few years of imprisonment, there would be less opposition to the present petition. There is, however, little certainty, if the effort succeeds, that Mrs. W—— will serve out a life-sentence. After a few years, when the public have forgotten the enormity of her crimes, she will quite possibly come out to repeat, it may be, the same diabolical deeds.

The condition of the insane is always a matter of interest, and generally also of commiseration, for the accommodations provided are rarely suitable for the requirements either of acute or chronic cases. The asylums of New York State are no exception to the unfortunate rule that the inmates do not receive the treatment necessary for their restoration to health and sanity. The State Board of Charities has recently made a very elaborate report of the condition of the asylums, and particularly of those in counties which endeavor to take care of their own insane. In these counties economy is sought rather than the best care, which is necessarily expensive. The result has been that the patients generally fail to secure the benefits they expect. The remedy which the State Board of Charities proposes, is to require the counties to send their insane to the State institutions, and then to make the cost of the care a charge upon the State rather than require the counties to foot the bill. A bill has been introduced in the New York Legislature carrying out these views, but it has not yet received favorable action. It is not anticipated that the counties will object seriously to the burden which they have already borne being assumed by the State. The importance of the matter will be at once seen when it becomes known that on October 1, 1887, there were in the County and State asylums combined 14,062 insane persons.

Acute Yellow Atrophy of the Liver and Phosphorus Poisoning.—Dr. Poore believes that all cases of acute yellow atrophy of the liver are due to phosphorus poisoning. Since the recognition of the marked changes occurring in the liver from taking phosphorus in overdoses, the cases of so-called acute yellow atrophy reported have been very few. If there is a true idiopathic acute yellow atrophy, it is clinically indistinguishable from phosphorus poisoning.—*The Lancet.*

SOME DEFENSIVE REMARKS ON THE CLIMATE OF MINNESOTA.

By T. J. HUTTON, M.D.,

FERGUS FALLS, MINN.

EMERSON says, "There is a crack in everything that God has made." If we must criticise, it were better to use the language of a pious departed prelate, "It did not please God to make this world perfect."

Of the great physical agents which most powerfully influence the human race—climate, food, soil, and the general aspect of nature—climate ranks first in importance; and in this matter of climate alone—not to speak of food—how much acute and chronic grumbling there is on all sides, and in every land! Climatically considered, how few real Happy Valleys, or Felicitous Hill-sides there are! As a matter of fact, how few large classes of men are climatically contented. Herein the old woman's adage is true, "If it isn't one thing it's another." True, the Bermuda negro and the New Zealander *seem* happy in their sun and surf—if, indeed, these beings can be termed men. But in reality even these are not all happy. I have seen the Bermuda negro, on his "native heath," lathered in surf and saturated with "soda-water," gasp for breath on a hot summer day like a canine exhausted in the chase.

Throughout our country everybody claims to know all about the climate of Minnesota, but in reality very few—even of its own residents—are posted on its characteristics. My remarks on this subject, based upon ten years' residence and practice here, will be brief and practical—defensive, not panegyric—but, above all things, strictly truthful.

The climate of Minnesota is practical rather than ideal; severe but chaste; harsh but exceedingly healthful. Its distinctive qualities are due to its atmosphere, which is cold, dry, and pure; and its atmospheric peculiarities are due to geographical position, being at the centre of the continent, far from oceanic influences, and at the top of the continent, where its head-waters divide, and where, during most of the year, Sol's rays come slowly, feebly, and askant. Our winters are long, cold, and, toward the end, a trifle tedious, but the compensatory element is that they are pretty uniformly cold from beginning to end: one may know at the approach of winter what kind of weather is ahead; no rain, fog, mist, or drizzle; no rapid and low falls of the glass, causing slush and slough to appear; and—with proper food and clothing—these same cold winters are exceedingly healthful. The sensations experienced in this coldest air are friskiness, muscularity, and clear-headedness. As to the sensation of cold, or degree of suffering from cold, one hundred truthful observers will confirm this statement, viz.: five minutes' exposure to the March east wind in New York or Philadelphia will cause much greater suffering than thirty minutes' exposure here at our very lowest temperature. This difference is due to our air being dry. But we have a greater number of cold days—our winters are longer; briefly stated, this is the great, if not the only, objection to our climate.

The chief beauty of the Minnesota winter is that there is bright sunshine throughout, cloudy days being very few indeed. On the coldest days (there are three or four days of −40° F. temperature each winter) the sun shines with dazzling brilliancy. At such times the stranger within our gates, judging of the weather through the window, would think it a shame that the children were not out-doors playing marbles or jumping rope. The summers are short and bring some very hot days, but, the air being dry and the nights cool, there is perfect refreshment in sound sleep—a blessing not had in hot, muggy climates. Vigor being restored each night by sound sleep there is less discomfort by day, and the so-called summer disorders are very rare indeed. There is no regular spring season. Autumn is more pronounced. June and October are the pet months of the year. In June the foliage is fresh and dense, and then the tints of earth, sky, and water are the richest imaginable.

The climate of Dakota and Eastern Montana is similar to ours, and where good water abounds there is remarkable healthfulness. In proof of this, Valley City, a pretty county-seat in Dakota, itself containing a population of some two thousand souls, contains only one physician. Glendive, a pretty county-seat in Montana, containing a population of about one thousand—not to speak of the county at large—supports but one physician.

Dakota being more level and more treeless than Minnesota, old Æolus occasionally loses his grip on the winter winds. Then comes that famous phenomenon, "the Dakota blizzard;" and he who has breasted that gale may well be excused for quoting:

> "Go feel what I have felt,"

or comparing notes with that tourist who asks—

> "Can I forget that night in June
> Upon the Danube River?"

Let me relate a personal experience, which may convey a faint idea of this truly grand elemental behemoth. It is midnight in January. We are twelve miles (south) from home; rolling prairie intervenes. Our patient is at ease, we must start for home; for, like Byron's sailor,

> "Tho' the trembling mast quiver like a reed,
> Yet must I on."

It is cold, say −40° F. The still small voice of the blizzard is suggested by an ominous breeziness and a light snow, flying at right angles, some sixty miles per hour, like the

> "Swallow, swallow, flying south."

Soon the breeze stiffens and the snow thickens. I can no longer see my horses. Good God! I am all alone in a genuine Dakota blizzard, and ten miles yet to drive. And now, on full realization of the grandeur and the danger of the thing which encircles me, the mind assumes a peculiar state, like, in a general way, that of those who face death; only that this grand executioner robs death of its foul terrors, and gives it—I had almost said—a charm.

I am warmly clad in fur, so that I suffer nothing from the cold except my face, which is partly exposed, and which is duly searched by this due-north drive. In such air and at such pressure oxidation or tissue-metabolism is perfect, and this doubtless contributes to the mental elevation which, now as always, I have experienced in the blizzard. Indeed, the mental state is moral, sublime, or prophetic. It is not "Behold I show you a mystery," but "all mystery is about to be solved to you." It is the burning bush; it is Pisgah's height; it is transfiguration; it is the enchanted land of the "Arabian Nights;" it is Boreas and Thor come to take us to the heavenly mansions of Valhalla.

Real fear, sadness, or depression, there is none, for in this perfect oxidation mal-spirits are absent. The mind is incapable of depressing emotions, it is rather in a state of gentle elation, as in the martyrs who sang on the scaffold. It is no Tam o' Shanter affair; it is earnest, serious—yet a sort of mild Quaker joy. The law of chances or probabilities are against our ever reaching home; yet, thanks to our good steeds, after three or four hours of arduous toil (for them) we arrive there, and are soon at rest in the kind arms of Morpheus.

The real blizzard, whose spent fragments reach our northwest horizon, is, however, of rare occurrence, and is not an unmitigated evil. It constitutes a great Sabbath-day of nature's own making, a subject for talk, an epoch for reckoning, and a phenomenon of lively interest generally to the great majority of the population. As for the dozen or so of wayfarers who succumb to it in a decade they do not make a drop in the bucket to those whom falling brick-bats, street-car wheels, and other destructive agencies mutilate or destroy hourly in our cities, great and small.

Years ago I was called to resuscitate, if possible, a victim of whiskey and a blizzard. It was the first case of "frozen to death" that I had ever seen. Although the body was ice-cold, and stiff as a board, the eyes were

wide open and so preternaturally bright that for almost an hour, doubting it myself, I did not dare to tell his friends that he was dead; but rather felt to address him as a living being:

"If thou hast any sound, or use of voice, speak to me!"

This cold, dry, pure air possesses highly oxidizing, stimulating, and aseptic properties. Its low temperature, as well as its full supply of ozone, makes it aseptic; hence opposed to fermentative and microbic disorders. Its tonic and stimulating properties invigorate all the cellular elements, organs, and functions; hence it renders the causes of many diseases inoperative, and by the special tonus imparted disease of all classes is more readily resisted. By perfect oxidation self-waste is consumed; hence there is here but a minimum of the languor, ennui, and malaise which attend mal-oxidation and which constitute the modern evil spirits of humanity the world over.

This climate is too harsh for the nervous, the refined, the aged, and the feeble beyond power of rude reaction. It will not produce eminent poets or centenarians, neither will it generate dudes, dreamers, fools, or hypochondriacs. Rugged physique, rugged vitality, and a keen, rugged mind are the products of such a climate. The typical Minnesotian is a vigorous animal and a rustler. He has a mission to perform. He cannot sit still on a fence or dangle his limbs from a store-box. He cannot be idle. The restless genius of his "native air" says in tones of silent thunder, which must be obeyed, to everyone of him, "John, go and do something," and he does it. Even if he wish to, he cannot be a sluggard. He has his choice to hustle or to migrate. His air compels thought, consciousness, action. He may not live as long in his dry, highly ozonized air as in one moister and milder; but here he enjoys a keener and more cheerful sense of being, and does not run the gamut of the host of ailments which in moister and milder climates slay by the wayside.

There are fewer objections to be made to this than to most climates. Due to better body-tonus and asepsis—both the product of our air—there are fewer diseases here; these prevail less than elsewhere, and are attended by a lower mortality. The rarity of some of the commoner ailments which decimate mankind in milder and moister climates is simply marvellous; and I believe that the people of this State pay less money for drug-bills and doctor-bills per thousand population than any other State in the Union.

Dry nasal catarrh and diphtheria are the only prevailing diseases. The former is the fault of the climate, but it is so slight that it rarely calls for medical aid. The latter occurs in rural log-houses chiefly, and is due to neglect of ventilation. The fungus which generates this malady could find no better field of activity than in the dark, muggy air of these air-tight log-houses. But this is not the fault of the climate.

A few illustrations are now in order as to our healthfulness, based on the rarity of what are everywhere denominated "common disorders." Dyspepsia is not a disease of this climate; the Minnesota appetite is proverbial. Due to the special body-tone which I have repeatedly mentioned, obstructive disorders and those resulting from flabby and relaxed conditions of body scarcely occur here. Biliousness, bilious fevers, agues, do not belong here. Passive congestions, dropsies, diarrhœas, hemorrhages are very rare indeed. I have not written three prescriptions per summer for diarrhœa in the past ten years. Inflammations are also exceedingly infrequent.

I have treated but three cases of pleurisy in the past ten years. About a dozen cases of pneumonia have been seen in this time, the majority being alcoholics, and no case in the remainder attended with fatal results. Some six cases of acute bronchitis were seen, none capillary, and none fatal. Brain fever is said to result from low temperature, but I have never treated a case here in winter. Neuralgia and true rheumatism are also exceedingly rare. Many disorders are erroneously called rheumatism by the vulgar. I have not seen more than half a dozen or a dozen cases of acute rheumatism during my residence here; and, excepting a few cases of sciatica, I do not recall having treated any cases of neuralgia—so purifying to the blood is our air, and so soothing to the nerves, cold though it may be.

It appears to me that this climate is also a great ameliorator, if not curer, of cachexia, dyscrasia, and constitutional taints generally. There is here but a most meagre showing of scrofulous manifestations, and these are speedily amenable to treatment. Syphilis seems to die out in old and young. Cancer is not often encountered. I have seen here no phthisis originate in children, although the conditions of food, clothing, heat, and hygiene in general are not always the best. Occurring in adults, if not markedly hereditary, it responds well to appropriate treatment in the initial stage. Even when markedly hereditary, I have known this climate alone work many thorough cures. Four cases of this class come to mind as I write—two bankers, a lumberman, and a Catholic priest, who had all come from the East.

Let me observe here, parenthetically, that climatic benefits are far from being fully utilized. A few of the wealthier classes only avail themselves of climatic therapy; rarely is climatic prophylaxis resorted to; and still more rarely are homes selected in early life on purely climatic grounds. Yet if some climates are healthier than others—a proposition which admits of no dispute—such selection would find its basis in the soundest philosophy.

In conclusion, every climate has its distinctive drawbacks; no climate is perfect. I myself have grumbled in print over the transient asperities of our winter; but a liking for it continues to grow in me stronger and stronger every year. My objections then were based on long midnight midwinter drives of from twenty to fifty miles. These would be almost intolerable in any winter climate. The advent of railroads has done away with all such Herculean services. If men were governed either by pure instinct, which does not err, or by perfect reason, which is not yet attained, it would be difficult, if not impossible, to find a climate that, taken all in all, has fewer objectionable features than this. As it is, we do not know what is best for us; we whine like babes for things injurious, and at all times err and blunder. But, to quote Emerson again: "Here we are, that is a great fact; and if we tarry a little we may come to learn that here is best."

Treatment of Chronic Diarrhœa.—Dr. Debove claims great success in the treatment of chronic diarrhœa, especially of the tuberculous form, by silicate of magnesium. This remedy he administers in doses of half an ounce to an ounce and a half a day, suspended in a quart of milk. As a result the diarrhœa disappears. The silicate of magnesium is known under the name of *talc* or *steatite*; it is insoluble, inert, and has not heretofore been supposed to have any medicinal properties whatever. According to Debove, it promotes the healing of intestinal ulcerations, but seems only to be efficacious by its presence in large quantities. Debove says it is readily and rapidly eliminated from the intestines.—*The Boston Medical and Surgical Journal.*

Spontaneous Fracture in a Sarcomatous Tibia Followed by Bony Union.—In this case, which came under the observation of Dr. Valat, of Paris (*The Annals of Surgery*), the sarcoma appears to have been a slowly growing one of central origin. The first fracture occurred some months before any tumor was noticed. The patient got about with crutches until a year later when a second fracture occurred. This slow evolution raised the suspicion of hydatid disease, but an exploratory puncture set the question at rest. After death it was found that both fractures had united by good osseous union, a very rare occurrence in the case of sarcomata of bone, and one which tends to prove that the usual failure to unite simply depends on the rapid progress of the tumor.

ATONY OF THE RECTAL POUCH, AND ALSO OF THE ANAL SPHINCTERS: ITS ETIOLOGY, PATHOLOGY, DIAGNOSIS, AND TREATMENT.

By WILLIAM BODENHAMER, A.M., M.D.,

NEW YORK.

Atony of the rectum, as its name implies (atonia, ἀτονία, from ἀ, privative, and τόνος, tone), consists essentially of the loss, to a greater or less degree, of the tone or contractile power of the muscular coat of the organ. It is not a true paralysis, such as occurs in paraplegia, but merely a local impairment of muscular contractility.

Comparatively few authors have written upon the subject of this affection, although it is of much more frequent occurrence than is generally believed; and most all those who have noticed it, denominate it either *constipation, distention, dilatation,* or *relaxation,* of the rectum. But these terms are employed in a loose and unscientific manner, and this simple circumstance shows that the subject has not been well studied; indeed, these terms are entirely too vague and too indefinite to denote the true nature of the malady, they merely indicate the cause or the effect, but not the affection itself, consequently they are misleading.

With regard to the term *constipation,* it is derived from the compound Latin word, *constipo,* formed from *con,* together, and *stipo,* to cram, or to fill up close. The corresponding term *obstipato,* by which a form of costiveness is frequently described by Latin authors, is from *ob* and *stipo,* to obstruct, hinder, or stop up. The true import of the word *constipation* would therefore appear to be a mere collection or impaction of excremental matters in some part of the intestinal canal, the residuum of the various processes concerned in alimentation. It is obvious therefore, that constipation cannot be considered a disease, being, as it were, a mere collection of impacted fecal matter; yet it is nevertheless, the cause of many diseases, and is also often the sequel or result of disease.

The accumulation and impaction of the fæces in the pouch of the rectum is most always the result of the habitual neglect to attend strictly to the calls of nature in regularly emptying the organ; consequently the collected and impacted fecal mass, by its presence, mechanical pressure, and abnormal distention of the parietes of the rectum, causes the affection in question; and it may be observed, too, that in such cases, the protracted presence of the indurated fecal matter obtunds the organic sensibility of the organ, so that it requires something more than the accumulation itself to stimulate it to the expulsive effort. It may, indeed, be also remarked here, that while the impaction of fecal matter is the immediate cause of the atony, in such cases, the want of attention to the demands of nature in regularly evacuating the rectum is the remote cause. This defect of muscular power in the rectum, the result of prolonged distention of its walls, is similar to that familiar condition which takes place in the bladder when the calls to empty it are postponed too long; in this case the organ will not respond when the effort is made to relieve it, so that catheterism must be resorted to should simpler means fail.

The rectal impaction of fecal matter may, on the contrary, however, be the sequel or effect, instead of the cause of atony, as when some other cause has previously produced it. In such a case the accumulation is permitted to take place, because the rectum is powerless to completely expel it. As for example, atony, or the loss of rectal power, is frequently caused by the long continued pressure of the head of the child upon the inferior portion of the rectum, during a difficult and protracted labor. The writer has seen a number of such cases, and they are quite familiar to gynecologists, and are sometimes difficult, if not impossible, to entirely relieve; he has observed some such cases who for months or years after the accident, had not the power to expel indurated fæces without a resort to artificial measures. It is also well known that atony of the rectum is sometimes produced by the pressure upon the organ of ovarian tumors, uterine fibroids, uterine displacements, and the gravid uterus.

In certain conditions of the stomach and bowels, there is often an excessive quantity of gas generated, which accumulates in the colon and rectum, and which of itself, independent of fecal impaction, causes constant distention of these organs, and thereby produces atony of the same. Indeed, the writer must not omit mentioning here that the abuse, or the too frequent use of effervescing or gaseous products, as some mineral waters, or other waters charged with gas, etc., are also fraught with mischief, by the gas producing constant undue distention of the walls of the intestinal canal, more especially in the colon and rectum, into which it so readily passes, and in which it is more or less detained, and thus induces the disease in question.

Now, as to the terms *distention, dilatation,* or *relaxation,* it is evident that each one, like *constipation,* can only be properly used to designate the cause or the effect, as may be, instead of the atony itself. As an evidence of the improper use of the term *constipation* to designate atony of the rectal pouch, will at once appear by the manner in which it was used by the distinguished M. Brétonneau, of Tours, France, who, a number of years ago, met with many cases in which he found "great dilatation and torpor of the rectal pouch, forming as it were, a greatly enlarged place for the lodgement of fecal matter, which sometimes accumulated in it to such an extent as failed to be expelled." This plainly described atony of the pouch of the rectum he called *rectal constipation,* and astonished his contemporaries by the recommendation of powerful tonic and astringent injections, remedies such as are usually employed in diarrhœa, etc., instead of the active purgatives generally used to cure constipation. But viewing the disease as atony, and not constipation so called, the tonic and astringent injections of M. Brétonneau were both highly proper and rational, as will be shown. Constipation, as it is called, has generally been attributed to torpor of the liver, and the most active concentrated cathartic remedies in the form of pills, etc., were employed to arouse the indolent organ; whereas, on the contrary, in the affection under consideration, the torpor is in the rectum itself, and can be relieved by much milder, safer, and more certain means.

The writer thus far has been explicit upon several points, perhaps to prolixity, but he found great discrepancy in the descriptions and statements of various authors regarding this affection.

The loss of tonicity, or defective muscular power in the rectum, especially in its pouch, rendering it incapable of properly expelling its contents, is of much more frequent occurrence than is generally believed, and is doubtless often overlooked and diagnosticated as constipation of the bowels, and treated as such by the use of various purgative remedies. It is an affection which is attended by much distress, inconvenience, and trouble, and is liable, unless relieved, to result in serious injury, not only to the rectum itself, but also to those organs in its immediate vicinity. Indeed, whether the atony is due originally to the distention of the rectum by impacted fecal matter, or from some other cause, it cannot continue long without also seriously affecting the peristaltic movement of the organ.

Some of the causes and symptoms.—To enter fully into the causes, symptoms, rectal reflexes, and consequences of this affection, would far exceed the limits and objects of this article. A few observations, however, upon the most common causes and sequelæ of atony of the rectum, in addition to those already given, will be considered.

The most common remote cause of atony of the rectum is, perhaps, the habitual disregard of the calls of nature to relieve the organ, as previously remarked. It is demonstrated by the anatomy and physiology of the

rectum and anus, that nature has designedly made provision for the accumulation as well as the retardation of the fecal matter in the rectum, by furnishing this organ with a pouch or ampulla, and its extremity with a muscular mechanism, in subjection to the will, for the purpose of opening and closing it. This controlling and restraining power, when properly and duly exercised, is highly essential to our comfort and convenience; but when it is abused, in order to postpone or to set aside the admonitions of nature, so as to retain the excremental matter beyond the period when nature calls for its expulsion, serious consequences, sooner or later, will inevitably ensue.

It may also be proper here to remark, that not an unfrequent cause of atony of the rectum is that some persons, especially females, are in the constant habit of daily using warm or hot water injections into the rectum for the purpose of evacuating this sometimes torpid organ; but, by continuing this pernicious practice, the rectum is soon deprived of all the normal power of evacuation by its own efforts. It must be obvious to all experienced practitioners that the continued employment of either warm or hot water enemata, for the purpose of daily relieving the bowels, is injurious; for while it is true that by their first impulse they induce the peristaltic action, their reaction is always followed by the muscular fibres being left more or less softened, relaxed, distended, and deprived of their contractile power. These objections do not apply to cold water injections at the ordinary temperature; therefore, if such persons are compelled to use enemata in these instances, they should employ cold water, instead of warm or hot water, by which they would more easily attain the end they have in view and avoid the inconvenience of diminishing, more and more every day, the contractile force of the muscular fibres of the rectum, and thereby increasing the degree of their tonicity; for it is an established fact that the reaction of the cold water leaves the muscular fibres of the rectum more vigorous, more natural, and more effectually disposed to peristaltic action; whereas the reaction of either warm or hot water leaves the muscular fibres of the organ relaxed and enervated, consequently neither warm nor hot water injections should ever be used in atony of the rectum, as their tendency would be to induce the disease instead of curing it. But the abuse, or the too continued use of large cold water injections may also produce atony, as they, by their large quantity or bulk, unduly dilate the walls of the rectum and thus impair the power of its muscular coat.

Symptoms.—Some of the most prominent symptoms of atony of the rectum may be summed up as follows: There is generally experienced, in confirmed cases, a sensation of fulness or weight in the rectum, and a frequent desire to stool; but an evacuation, even when effected, does not altogether appease the desire, but leaves an uneasy feeling, as if some fecal matter still remained, with not sufficient power to expel it; defecation is sometimes attended with tenesmus and forcing pains, and a discharge of mucus streaked with blood, or a discharge of fluid fæces, which may have passed by a fecal bolus, lodged in the rectal pouch, and which may lead to an erroneous diagnosis of diarrhœa. In some of these cases the pouch of the rectum becomes dilated to an almost incredible extent, and filled with fecal matter, so that this distended viscus will sometimes be found to occupy a large space of the pelvis; while at the same time the organ makes but little or no effort to dislodge the accumulated mass; if the finger or the bougie be now introduced per rectum, it will readily encounter the rectal bolus, and at once determine the nature of the case. The bladder, urethra, and the other contiguous organs, often participate in the irritation produced. In men the prostate gland and neck of the bladder become affected, and in women uterine irritation and frequent micturition are the results. In such cases, whenever the rectum is completely evacuated, there is often experienced a distressed feeling of weakness in the loins, and sinking, with a want of the usual muscular tension, until the organ again becomes moderately replenished. On a specular examination of the empty rectal pouch, in the worst cases, it will be found abnormally enlarged, and presenting a smooth membranous bag, from which it would be difficult to expel indurated fecal matter, by the natural efforts. In some instances, however, the pouch will be found to be partially filled with enlarged folds of loose mucous membrane, which, when making defecating efforts, sometimes pass down into the fossa, between the internal and external sphincters of the anus, blocking up the narrow canal, and impeding the evacuation of the fæces, and also, to some extent, forming an impediment to the introduction of instruments and enemata. This morbid condition of the mucous lining is doubtless the result of a neglected state of the bowels. Indeed, this affection, if neglected or mismanaged, not only may give rise to internal prolapsus recti, but also to an intussusception of the superior and undilated portion of the rectum, into the dilated pouch, the inferior portion, and it may also give rise to a painful state of the anal sphincters.

Atony of the rectum and colon is most commonly met with in delicate females of a lax muscular fibre, and in those whose sedentary occupations lead to a neglect of the necessary measures to insure regularity of the functions of the organ. It is also frequently met with in delicate children.

Treatment of atony of the rectal pouch.—In the treatment of defective muscular power of the pouch of the rectum, it is of importance not only to be able to recognize the true nature of the malady, but above all to know also the most rational and effectual measures for its relief. The first consideration in the treatment of this affection is to enjoin a strict observance of regular habits, regarding a daily evacuation of the rectum, and this desirable object in mild cases may be aided and often attained by simple means, such as the injection of from half to one pint of cold water into the rectum, at the regular time of going to stool every day. This constitutes a most valuable remedy in atony of the rectum; cold, being tonic, stimulant, and astringent, acts somewhat similarly to nux vomica, by exciting the sensibility and contractility of the organ, but should be discontinued as soon as the object of its use has been attained.

In the more obstinate cases, however, the chief remedies should be nux vomica alone, or in combination with some other suitable ingredients, together with the employment of rectal injections, composed of powerful astringent and tonic substances, with the intention of producing contraction, corrugation, and condensation of the weak and relaxed muscular fibres of the rectal pouch, by which they become shorter, stronger, and firmer, and thus aid in diminishing the morbidly enlarged pouch to its normal dimensions and tone.

The exhibition of proper aperients, as adjuvants, are indicated in some of these cases, and cannot be dispensed with, especially when atony of the colon exists with that of the rectum. But drastic purgatives should not be used, for they, as a general rule, do more harm than good in such cases. The smallest dose of an aperient should be given, so as to gently rouse the normal peristaltic action, and only to continue its use until a habit of daily evacuation is induced. The object is, by no means, to excite watery stools, but to induce, as much as possible, an imitation of the normal action of the bowels. Indeed, the best and only method to keep a regular action of the bowels, after the habit has been re-established, is to compel them, if possible, to perform their own legitimate work, by withholding aperients, as well as all the other artificial means generally used for this purpose. With regard to the ingredients composing the astringent and tonic injections to be used in the treatment of atony of the rectum, such substances abound, and may be varied indefinitely by the practitioner. These injections should not exceed in measure more than five or six ounces, and should not

be administered until the rectum has been previously emptied of its fecal contents by a proper enema or an aperient. The astringent injection should be given at least once daily, and retained for a few minutes, if possible, but if it cannot, and is passed at once, it will nevertheless do good. In obstinate cases, it may be of advantage to add from one-half grain to one grain of nux vomica to each injection.

The writer has used, with good results, in some of these cases, the decoction of galls, as well as a strong decoction of white oak bark and alum. He has also used the following:

℞. Acidi tannici..... gr. xx
Claret wine..... ℥ iv.
Fiat injectio.

M. Brétonneau, in order to correct the morbid condition of the rectal pouch in these cases which he called rectal constipation, and which he often found complicated with anal fissure, used with signal success, according to the testimony of his distinguished pupil, M. Trousseau, the following injection, which not only restored the organ to its normal tone and action, but also cured the anal fissure when both affections co-existed:

℞. Ext. rhataniæ..... ʒ ij.
Sp. vini rectificati..... ʒ v.
Aq. puræ..... ℥ iv.
Fiat enema.

The writer has employed with success the injection of M. Brétonneau in a number of cases, and among them several children, in which from one-half to one-fourth of the quantity only was injected.

In some of these cases the following pill, or a somewhat similar one, may be used with advantage, especially when atony of the colon exists with that of the rectum, so as to excite the peristaltic action, and soften, if possible, the fecal matter in the former, as it cannot in its entirety be so easily reached by injections. One pill should be taken at dinner or at bedtime:

℞. Extr. aloes..... gr. xxx.
Extr. nucis vomicæ..... gr. xx.
Extr. hyoscyami..... gr. xv.
Sulph ferri..... gr. x.
Ol. caryophylli..... gtt. v.
M. et divide in pilulas xxx.

Or the extract of nux vomica may be advantageously given alone, once daily, in the form of a pill, of from one-half a grain to a grain.

Galvanism.—In atony of the rectal pouch galvanism may also be employed. A properly directed current to the seat of the affection might stimulate the coats of the rectum to such an extent as to aid in restoring their lost tone and action, and thus ultimately produce normal peristalsis.

Mechanical removal of impacted fæces.—In cases in which the rectal pouch is firmly distended and blocked up by a large, hard fecal bolus, or by a large, soft, and tenacious mass, neither purgatives nor stimulating injections will have any effect toward softening and removing the former, nor dissolving and removing the latter. The only remedy in such cases is the employment of mechanical means. After dilating the anal sphincters well, under etherization if necessary, the fingers, with the aid of the rectal curette, should be used to break up and remove as much of the impacted mass as possible, and the remaining fragments should then be completely washed out by stimulating injections.

To all these means, in the treatment of rectal atony, must necessarily be added, as auxiliaries, a proper tonic diet, claret wine, exercise in open air, etc.

Atony of the anal sphincters.—The loss of tone of the sphincters of the anus, like that of the rectum or rectal pouch, and from somewhat similar causes, sometimes occurs and consists of the loss of power to some extent of their muscular fibres. In such cases, although the sphincters lose a large portion of their tonicity, yet their functional power is not altogether destroyed as it is in paralysis the result of paraplegia, in which both their grasping and retentive functions are entirely lost, so that the dejections, if fluid, will, on reaching the sphincters, escape involuntarily. The anal sphincters are much less frequently the seat of atony than the rectal pouch, but the affection in both may, and does occasionally, co-exist. When the sphincters are affected the disease is more readily detected, being external, but when the rectal pouch is the seat of the affection, it is much more liable to be overlooked, being internal.

Atony of the sphinctores ani frequently occurs in old age, and in such it is commonly called palsy, or local paralysis. It is a very troublesome and distressing affection, and often attended by prolapsus recti and eversion of the anus; and it sometimes entirely prevents the aged patient from taking any exercise on foot. It is one of the worst forms of atony of the anal sphincters, if it may in reality be so called, being so closely allied, as it were, to partial paralysis that it is difficult to distinguish between it and such an affection. This form, however, in these cases, is generally without any marked disease in the nervous centres affecting other functions also. Atony of the anal sphincter is often met with in some hysterical women, and also among hypochondriacs; and it sometimes occurs in infancy and childhood.

Among the causes of this affection may be mentioned: Exhaustion from protracted ill-health; sedentary habits; the immoderate use of alcohol and tobacco; excessive or repeated dilatation of the anus, produced by the straining efforts at evacuation in chronic dysentery; divulsion of the anal sphincters, either for therapeutical or diagnostic purposes. The affection is sometimes produced by a descent, or prolapsus of the rectum, or hemorrhoidal or other tumors of the same, which, by their continued pressure within, and their frequent passage out and in through the anal orifice, impair the contractility of the anal sphincters. In such cases, however, as a general rule, the removal of the cause will restore the sphincters to their normal tone. Among the most fertile causes of anal atony, according to some authors, may be mentioned the indulgence of unnatural congress.

By the action of the anal sphincter, the skin of the anus is disposed into radiated plaits, with intervening furrows, which extend some little distance into the anal canal, as well as out on the external surface. In atony of the sphincters, these folds or wrinkles almost or entirely disappear, or become effaced, the margin of the relaxed anal orifice will be found loose and salient, so that the finger or bougie can be passed through the anal orifice into the rectal pouch without meeting any resistance. When the atony is the result of vicious habits the anus is much excavated, as it were, and presents the aspect of a funnel. In all cases of anal atony there is a slight escape or oozing of fecal matter for a short time after each evacuation, so that it is almost impossible to observe strict cleanliness during that period.

Treatment.—In the treatment of the ordinary cases of atony of the anal sphincters, the cold ascending douche is a most valuable remedy in restoring their lost tone. It should be applied to the anus forcibly for four or five minutes, immediately after each evacuation of the bowels, and once or twice besides during the twenty-four hours. The following ointment or lotion may be used with advantage in such cases:

℞. Strychninæ sulph..... gr. x.
Unguent. aquæ rosæ..... ʒ j.
Fiat unguentum.

℞. Extr. nucis vomicæ..... gr. viij.
Alcoholis..... ʒ ij.
Aquæ ammoniæ..... ʒ j.
Fiat lotio.

Galvanism, as well as nux vomica, should also be employed in these cases.

NODOSITAS CRINIUM; OR, TRICHORRHEXIS NODOSA.[1]

BY RICHARD COLE NEWTON, A.B., M.D.,

MONTCLAIR, N. J.

GENTLEMEN: I have chosen to speak to you this evening upon this somewhat obscure affection of the hair (mostly of the beard), because I have had peculiar facilities for studying a case of it, and because it is one of those complaints which, owing to the rather vague and unsatisfactory nature of its literature, may prove a stumbling-block in the way of anyone of us.

Beigel, in 1855, first described it under the title of "Auftreibung und bersten der Haare."[2] Wilson, however, had written of practically the same affection, in 1849, under the title of "Fragilitas Crinium." Wilks is said to have recognized it in 1852, but did not publish his observations until 1857.

In America nodositas crinium is undoubtedly very rare. Bulkley[3] met with it four times in eight thousand cases of skin disease. Of these four cases one will shortly be described to you in detail. Jackson has seen two cases.[4]

It is easy to imagine that any contribution to the clinical history of this complaint may be valuable. Its etiology, progress, and treatment are more or less involved in uncertainty.

The name of trichorrhexis nodosa is said to have been suggested by Kaposi. Other names have been brought forward, *e.g.*, clastothrix, Wilson; tricoptilosis, Divergie; trichoclasis, Fox, etc. I have ventured to suggest the name which appears at the head of this paper, Nodositas crinium, because (1) trichorrhexis nodosa is a cacophonous hybrid, an unnecessary mixture of Latin and Greek; (2) because in the affection, so far as I have been able to observe it, there is no spontaneous bursting of the hair, as the term trichorrhexis would seem to imply; (3) because the term fragilitas crinium is already in use in our nomenclature, and nodositas crinium is similar in derivation and of obvious meaning; (4) because fragility and nodosity of the hair generally coexist in the same subject;[1] and nodositas crinium, or, if you like, nodositas et fragilitas crinium, seems to me to express our meaning better, and to be a smoother and more intelligible title for the condition. I should add that Behrend has, for a similar affection (in *Virchow's Archiv*[2]), proposed the name of nodositas pilorum Smithii, which, however, he differentiates from trichorrhexis nodosa.

My first case of nodositas crinium occurred in a medical friend, who has been more or less intimately associated with me, and has been almost constantly under my observation for eleven years, ever since the disease first appeared. In the following history I shall draw largely from his own notes of the case.

CASE I.—In February, 1878, O. A—— first noticed, quite by accident, what seemed to be nits upon the hairs of his beard. The affected hairs were chiefly at the corners of the chin and over the rami of the jaw. The beard at the affected spots was peculiarly dry and lustreless. The mustache was not involved. My friend was then twenty-six and a half years of age. He was in fair health; was an interne in one of the large hospitals in New York City, and had many duties to attend to. His family history is not especially significant. His father had lost much of his hair at twenty-nine. He had been an exceptionally vigorous and active man, and had died at fifty-four, of what was said to be leucocythæmia, although A—— thinks that his father's final illness was typhoid fever.

His mother died at forty years of age, of carcinoma, apparently produced by rapidly succeeding pregnancies. He has lost two brothers of acute diseases, and has four sisters living and well. Nothing like nodositas crinium has ever been known in the family.

No suspicion of a specific taint, hereditary or acquired, can be entertained.

A—— had worked on a farm in his early life, and in college had been fond of athletic sports. He was exceedingly strong and muscular. In college he had been somewhat annoyed by cardiac palpitation. He thought that he might have "strained" his heart in the gymnasium, although probably his trouble was tobacco-heart. He has outgrown the cardiac difficulty. He has an idiosyncrasy with regard to tobacco; sometimes smoking and enjoying it, especially at times of excitement or change, as when about to undergo an examination, or upon a long journey. Then a distaste for tobacco will supervene, and A—— has gone for months or years without touching it. He has also this peculiarity, with respect to quinine, that ten or fifteen grains of the drug, taken immediately before bedtime, is a most agreeable and efficient hypnotic.[3]

In the winter of 1883 and 1884, A—— was in the Indian Territory, and was having now and again "chills." After each of these he noticed that his nodositas was worse.

To return to the history of the earlier manifestations of this curious malady. A—— states that he had had various neurotic pains during the "cram quiz" which he went through to obtain his hospital appointment. The most marked of these was an aching pain in the back of the neck. He had relinquished the use of tobacco some years before; but, having accidentally discovered that smoking would allay the pains referred to and promote sleep, he began smoking again, and went on with his quiz. He was obliged to teach most of the time while studying medicine, and had met with some rather serious disappointments. His own opinion is that severe nervous strain brought on the nodosity.

He showed himself to Dr. Bulkley in 1879. He had then shaved his beard for over a year, under the impression that the nodositas would pass away of itself, or be

[3] Dr. Beigel (Reynolds' System of Medicine, vol. v., p. 379) calls attention to the direct action of this drug upon the sympathetic nervous system in functional nervous disease, and states that Duméril, Demarque, and others are of similar opinion.

cured by shaving. Dr. Bulkley, after carefully examining the case, assured A—— that there was nothing parasitic about it, and directed him to shave for three months, using every night a thorough inunction of vaseline, and then to let his beard grow, still using the vaseline. This treatment was faithfully carried out, and, while it mitigated the condition, it did not cure it.

It would weary you were I to give you a detailed account of the various measures which my friend resorted to for the cure of his nodositas. He had tried complete and repeated epilation of all the diseased hairs (which promptly grew again), mercurial inunctions in several forms, pustulation with croton oil, boric acid ointment, chrysarobin, carbolic acid, carbolic salve, etc. At my suggestion he used sulphur ointment faithfully for three months, all to no purpose. He also took arsenic until its constitutional effects appeared; afterward iodide of potash to a like extent; then tincture of iodine. He had also taken strychnine. In 1885 A—— was in excellent general health, but his nodositas was just the same, or worse. It occasionally appeared in his hair, but always disappeared from there spontaneously in a short time. From the beard, however, it was never for any length of time absent. Always, after any manifestation of malaria, the trouble was worse. A—— says when he would allow his beard to grow, in a period of time varying from ten days to six weeks, the nodositas would appear; in two or three days more the hairs would split and break, and then would act like foreign bodies, setting up considerable itching, which could only be relieved by shaving.

The nodositas never appeared in the mustache.

In 1885 he tried the liquor potass. locally, also cantharides, glycerine, and bay-rum, and two secret remedies —the last more to please his friends than because he had any faith in them. He then gave up the battle and has shaved his chin and part of his cheeks at least two or three times a week ever since.

In the summer of 1888 another functional nervous disturbance showed itself, *i.e.*, insufficiency of the internal recti muscles, for which my friend consulted Dr. C. S. Bull. This is now very much better and his general health is excellent. His weight is one hundred and ninety-eight pounds, and he is, as he always has been, a very active man. His nodositas is better, in that he can wear a moderate-sized pair of side-whiskers.[1]

CASE II.—In 1885–86 I had a patient, forty-five years of age, E. R——, who was fairly well nourished, but somewhat anæmic. His mother, after suffering from her nerves all her life, died insane. His brother was, as E. R—— expressed it, "cranky." His father had reached a green old age. When I met E. R—— he was always constipated, was subject to terrible migraine, which was accompanied by nausea, strabismus, and diplopia. Morphine, as a rule, only excited him. He smoked in great excess and had a nervous polyuria. He was a man of considerable intelligence, and from his description of a disease of his beard, the like of which he had never seen, I knew at once that he had suffered from nodositas. From this he had recovered a year or two before I saw him, and attributed his cure to a nostrum containing sulphur. His general health had, however, improved greatly, and his weight had increased forty pounds since his nodositas had appeared. There was, to my mind, always an hysterical element in his nervous troubles. There was no reason to suspect syphilis.

I have related with some minuteness two cases of nodositas crinium. I will quote Dr. Michelson's[2] conclusions as to the nature of this affection.

1. "The above mentioned expansions and fissures in the course of the hair-shaft are not separate diseases, but a morbid symptom—the expression of a morbid dryness and brittleness due to atrophy."

2. "Broom-like fissuring[1] and division of the shaft into larger longitudinal splinters are equivalent processes; both are initiated by the loss of the cuticle; they are often combined and largely merge into each other."

3. "The beard is the region of predilection of this disease, but its occurrence in the scalp is by no means rare. It is less conspicuous here on account of the smaller dimensions of the nodules."

As you will observe, Michelson[2] hardly dignifies this complaint by designating it a separate disease. In a case like O. A——'s, where the subject of nodositas seems to be in almost perfect health, we can hardly regard the affection as a serious one. A——'s detailed description of the gross and microscopical appearance of the hairs in his beard tallies closely with the conclusions of Michelson's given above, as did also E. R——'s.

The hairs were disorganized, swollen in places, split and fissured, and there is air not only in the shaft but in the root. Dr. Van Harlingen[3] states that air is normally in the shaft, and this air he says communicates with the atmospheric air. When the air gets into the root the hair is disorganized and dies.

Dr. Wolfberg[4] has a theory that nodositas is produced in the beard merely by rubbing it. This hypothesis is scarcely tenable when we reflect upon the numbers of people who habitually rub or fondle their whiskers and the great rarity of nodositas. Eichhorst[5] seems to attribute the affection to fatty degeneration of the medulla of the hair-shaft.

In conclusion, gentlemen, I am of opinion that the complaint is a pure neurosis and of little significance as regards the general health. One of my cases was a man who has not been sick in bed a day in twenty-one years, and who has always done considerable hard work, both physical and mental. He is undoubtedly prone to functional nervous disorders, from which he shows a strong disposition to recover. My second case showed a more marked nervous history; but a much more tractable nodositas.

I wish that I could give you some definite directions for the treatment of this disorder. All external applications whatsoever seemed useless in O. A——'s case. In E. R——'s the only treatment made use of was the lotion containing sulphur, and E. R—— was sure that it had cured his beard. If I meet another case I shall try cod-liver oil and phosphorus, as is recommended for alopecia areata. I shall use no external applications except occasionally something very bland, perhaps containing a little sulphur. O. A—— believes nux vomica taken internally to the point of toleration did his beard good; and perhaps it did. I should exhort my patient not to worry about his beard, but to shave with as good a grace as possible, and to take good care of his health; as this improves no doubt the nodositas tends to disappear, especially if the patient grows more fleshy. In this connection it may be worth while to call attention to Wilson's theory,[6] that baldness is commoner in men than in women, because of the thicker layer of fat which the latter wear underneath their scalps.

THE TREATMENT OF CORNS.—Dr. C. McDermott writes to the *British Medical Journal* that a saturated solution of salicylic acid in flexible collodion is an excellent remedy for corns. The corns should be painted twice a day. It takes about twelve days for their complete removal.

---

[1] Dr. Duhring relates a case of atrophy of the beard, similar to A——'s, in the American Journal of the Medical Sciences, July, 1878, p. 88. The condition was much more serious. The patient, also a young physician, thirty-three years of age, was in poor health and no nodosities were present, at least after Professor Duhring saw the case.

Clinical Department.

PLACENTA PRÆVIA, WITH SPONTANEOUS ARREST OF HEMORRHAGE.

By M. A. DUMOND, M.D.,

WEST DANBY, N. Y.

In view of the great mortality attending placenta prævia, I take the liberty of presenting the following unique case, as I have no knowledge of a similar one. I was called in haste, on the night of December 9th, to see Mrs. K——, twenty-three years of age. Pregnant about seven and one-half months with her third child, she had been suddenly awakened from sleep by a very profuse hemorrhage, which had ceased before I arrived. My suspicions of the cause of the flooding were that it was from an abnormal position of the placenta, and this view was confirmed by examination, as I found that peculiar doughy feeling imparted to the touch that is so indicative of trouble ahead. I advised them of future floodings, and, as she was some four miles from a physician, with roads that are almost impassable at this season of the year, I was very anxious on her account. Again, on the night of December 21st, there was another serious hemorrhage. The case now looked serious, and I asked to have my friend Dr. Murray, of Van Etten, see her with regard to the advisability of inducing labor. We concluded to hold on a short time and await results. I was again summoned, on the night of January 2d, as labor-pains had commenced, and with them, as I had anticipated, flooding. Upon my arrival I found the child in the hands of the nurse; the mother weak, but in fair condition.

Upon inquiry I found that with the first appearance of pains there was a severe flooding, which stopped, however, after a strong contraction. Then the question was, what was the cause of its sudden stopping? On further inquiry I soon found out. The child was born feet first. The contraction had forced it down and separated the placenta on one side of the uterine neck, and thereby made an efficient tampon. The case, of course, after that time presented nothing of interest, except that the nurse was fortunate enough to deliver the child in time to save it as well as the mother. Here is a case in which an uncommon presentation, to say the least, saved the woman's life.

A SUB-SPINOUS DISLOCATION OF THE HUMERUS REDUCED AFTER FIVE MONTHS, WITH GOOD RESULTS.

By J. E. MOORE, M.D.,

MINNEAPOLIS, MINN.

Mr. M——, aged forty-three, came to my clinic at the University on January 15, 1889, with a dislocation backward of the left humerus of five months' standing. He gave no very clear history at that time of the cause of the dislocation, but said that it had not been recognized by the attending physician until two months after the accident, when an unsuccessful effort was made to reduce it under ether.

The head of the humerus could be felt distinctly on the dorsum of the scapula, beneath the spinous process. Duga's test failed because the inner condyle of the humerus could readily be brought against the side of the chest. The shoulder was quite sensitive, motion limited, and arm almost useless. Chloroform was administered, and after breaking up very firm adhesions I succeeded in overcoming the deformity by placing my heel against the coracoid and acromion processes and making traction forward and outward on the arm. When the arm was strongly adducted, or rotated inward, the head of the humerus slipped out of the glenoid cavity. It was very easy to reduce the deformity after the first time, but very difficult to keep it in position. Adhesive strips were applied in such a manner as to draw the upper end of the humerus forward and the lower end backward. The next morning the parts were just as they had been left, but in the evening the deformity had returned, although not so marked as before.

On January 19th chloroform was again administered and the head of the humerus brought into proper position. The patient was then brought to the edge of the table, lying on his back in such a manner as to fix the scapula. The arm was then extended to a right angle with the body, and the back of the hand pushed well down toward the floor.

While an assistant held the arm in this position I folded my hands over the back of the humerus close to the patient's body, and made very strong traction upward and forward. I felt a tearing as if more adhesions were being broken up, and the head of the humerus slipped well forward. Adhesive strips were applied as before, and the patient was put to bed. After this no difficulty was experienced in keeping the parts in place.

January 24th, was summoned hastily, the messenger stating that my patient was crazy and suffering great pain. I then learned, for the first time, that he was subject to occasional attacks of epilepsy, and that he had had three spasms in succession that morning. I found him sitting on the bed, complaining of great pain. Upon examination I found the adhesive strips just as I had placed them and the shoulder all right. He then told me that it was not that shoulder but the other one that gave him pain. Upon examination I found the right shoulder dislocated directly backward, just as the other one had been. It was readily reduced by manipulation.

His brother informed me that the former dislocation, as well as this one, had taken place during a spasm, and while the patient was upon his back in bed. He stated that he had been with the patient both times, and that no great effort had been made to hold him.

I conclude, therefore, that the dislocation had been caused in both instances by muscular action alone. After two weeks I began passive motion, and at present writing, March 8th, he has almost perfect use of both arms.

CONSERVATISM IN MINOR SURGERY, WITH SPECIAL REFERENCE TO INJURIES OF THE FINGERS.

By O. J. FULLERTON, M.D.,

WATERLOO, IA.

Surgery becomes conservative when it tends to alleviate suffering without resorting to operative interference. From the foregoing statement it will justly be inferred that I mean by "conservative surgery" any plan that offers a reasonable assurance and a fair prospect of usefulness without involving a risk of life.

To deprive the human frame of any of its component parts, no matter how small, not only robs it of a portion of some form of force, but disturbs, as well, the harmonious interblending of its original and natural operative functions and usefulness. A finger may seem a small and unimportant member, yet of its utility and beauty there can be no doubt. Sometimes it is very necessary to have a finger as long as possible, and even the saving of a quarter, or an eighth of an inch, to the physician, musician, dentist, penman, and many others, is highly important.

The public are beginning to realize that the useful little member is sometimes needlessly amputated. Therefore, let there be no act of the surgeon which shall deprive the hand of any of its members, or in any measure impair its usefulness, unless there exists an absolute necessity for it.

The interests of humanity demand that we should realize the advantages of conservative surgery in all injuries. There is no doubt in my mind that many fingers, or parts thereof, are sacrificed in primary amputation

which could and should be saved by proper conservative treatment. I am persuaded that surgeons too often feel that their business is to cut whenever opportunity presents itself, forgetting that they would more fully and creditably perform their duty if they operated only in the event of no alternative.

Surgery is an enticing and brilliant art, covering with fame the men who have done the most to make it such; and yet it has a dangerous tendency, especially in the minor operations, because of the seeming unimportance of the members operated upon.

That there have been some failures in the effort to save counts for nothing. Let there be a halt called in this branch of surgery, and a united effort by the profession to turn the tide toward what I have termed "conservatism" in minor surgical operations. And true it must be that many of the results that are now unsightly, shocking, and fatal to the members operated upon would be less frequent.

Then carefully aid nature, the "great physician," and note the monuments of repair silently attesting and demonstrating the wonderful repairing power of Him who heals.

The class of individuals among whom "conservatism" is the most often called for are railroad employees and employees of our vast manufacturing establishments, whose injuries comprise simple and compound fractures, luxations, contused and lacerated wounds. And it is often not only difficult but impossible to determine the real extent of injury done to the soft parts until a sufficient length of time has elapsed for circulation to be re-established.

After careful perusal, I have been able to find but little surgical literature with special reference to surgical appliances and dressings of the fingers, except that which treats of the subject in a general way, and of which we all have knowledge I therefore wish to call your attention (so far as I know) to an original appliance and mode of dressing which, in my opinion, if adopted, will be the means of saving many a useful finger that would otherwise be lost or amputated.

For lack of a similar and more perfect splint in the market, I have been using for some time, in this particular class of injuries, a splint and dressing which may be prepared as follows. Securing an assortment of sizes of the common paper shot-gun shells, ranging from numbers eight to twelve, inclusive:

First, remove the capped end of the shell.

Second, remove about one-third of the surface of the shell by cutting from end to end in parallel lines, leaving the remainder of the shell, about two-thirds of which is in the form of a trough with rounded bottom and corners. We shall then have formed a slotted flexible tube. (I also believe that a similar splint, manufactured of wood or straw pulp, saturated with an antiseptic solution —the splint being of sufficient strength and size to fit any member of the body—would commend itself to the favor of the surgeon.) Always select a size that will nicely fit the finger.

Third, take a piece of surgeon's medicated lint, of sufficient size to encompass about two-thirds of the injured finger, saturate it with iodoform and glycerine, one part of the former to twenty of the latter, and place the prepared lint in the slotted tube.

Fourth, after a thorough antiseptic cleaning of the wound, if any, reducing any fractures or dislocations, and removing all hopeless fragments or spiculæ of bone, and, while extension is made by an assistant, place the finger in the slotted tube, securing it by adhesive strips passed entirely around the finger and tube, near each extremity. Dress antiseptically, and place in a sling.

Claims for this dressing.—First, it is neat, light, cheap, and simple. Second, it is flexible, and therefore allows for extension from swelling, by simply cutting adhesive strips. Third, by cutting a fenestra opposite the wound it may be inspected and dressed daily without removing the splint, at the same time affording the proper drainage. Fourth, the splint being in the shape of a slotted tube, and when applied giving both anterior and posterior, as well as lateral, support to the injured member, thereby securely retaining the fragment in perfect apposition. Fifth, the material of which this splint is constructed being such that the surgeon can, with a knife, in a moment adjust or perfectly fit the same to the injured member.

If, then, we have succeeded in directing your thoughts in a line that, when mature, will be the means of saving, for some unfortunate, only a fraction of his least finger, we will feel our efforts have not been in vain.

HOW TO STAIN AND TO AVOID DECOLORIZING THE TUBERCLE BACILLUS.

By K. A. NORDERLING, M.D.,

ROCKFORD, ILL.

For an expert there is not much difficulty in finding these microbes, even if they should be present in very small numbers. For the less experienced, however, there is considerable difficulty in their discovery on account of the great facility with which they are decolorized by the nitric acid if the prepared cover-glass should be in only a few seconds too long contact with the acid. Especially when the bacilli are very few in number this decolorization readily takes place, and they consequently become invisible.

The patient is then, on account of the negative result, pronounced free from tuberculosis, when he is in reality suffering from this disease.

Therefore, to be able to discover the bacilli, we must know of some acid or other agent that does not decolorize these microbes even after having been a long time in contact with them.

Such an agent we possess in oxalic acid.

The staining is done in the following way: One part of aniline oil is thoroughly shaken for a few minutes with ten parts of distilled water, and then filtered through a filter previously moistened with water. To the perfectly clear solution is then added four or five drops of a saturated alcoholic solution of fuchsin. In this solution (fuchsin aniline water) is immersed the prepared cover-glass. The solution is slowly heated a few minutes until vapor appears, then the cover-glass is taken out and washed in distilled water, and afterward immersed in a saturated solution of oxalic acid. It must remain here until it is completely decolorized, when it is taken out, dried, and immersed in a weak solution of methylin blue, until it has received a light-blue color (about one-half to two minutes). After this it is dried again, and examined in Canada balsam with a homogeneous immersion-lens. All is now colored blue except the bacilli, which have a beautiful red color.

I have tried several methods of staining, but in none of them are the bacilli seen so plainly and brilliantly as when the above method is used.

Darwin Consults a Doctor.—A very pathetic story is told by Darwin in the life of his grandfather, Dr. Darwin, of Derby. One day a patient entered the consulting-room of a London physician and detailed the symptoms of his illness. It was an obscure and difficult case, of a kind that was only imperfectly understood, and the London doctor confessed himself fairly puzzled. He could only say that the patient was in a most perilous state. "There is only one man in England who understands the disease," said the London doctor, "who understands cases of this sort, and you should go and consult him. It is Dr. Darwin, of Derby." "Alas!" was the answer, "I am Dr. Darwin, of Derby."—*Murray's Magazine.*

Comfort for the Young Practitioner.—The wise patient now saith unto himself: Why should I pay for advice when the free clinics are open unto me, for is it not written that a fool and his money are soon parted?

Progress of Medical Science.

THE TREATMENT OF FIBROID TUMORS OF THE UTERUS BY GALVANISM.—This subject, which is engaging the attention of so many gynecologists at present, has been studied by Dr. F. H. Martin, of Chicago, who publishes the following general summary of his views (*The Journal of the American Medical Association*, January 5, 1889). 1. A means of generating a continuous current of electricity of steady and uniform character, that can give an actual current-strength through a resistance of 200 ohms, of 500 milliampères, is necessary in order to obtain all the benefits of this treatment. 2. Fibroid tumors of small size can be completely absorbed by the proper application of strong currents of galvanism. 3. Hemorrhages from hemorrhagic fibroid tumors can be promptly cured by the local coagulating effect of the positive pole when it is applied intra-uterine. Severe neuralgias so often accompanying these troubles can invariably be relieved by three or four applications of this treatment. 4. When the cervical canal cannot be entered by any form of intra-uterine electrode, flexible or otherwise, after repeated trials, a negative galvano-puncture should be made into the presenting part of the obstructing mass of the tumor, and an artificial canal opened, which is to take the place of the impenetrable uterine canal in all subsequent treatments. 5. The intra-uterine electrode should in all cases be negative, unless there is hemorrhage or excessive leucorrhœa, when the positive pole is always required. The same patient may, however, present symptoms demanding the use of both poles at successive operations. 6. The strength of the current should depend entirely upon the amount of active surface of the internal electrode, and should be 25 milliampères for each square cubic metre of active surface in actual contact with the endometrium. If more is used the concentration of the current will be sufficient to cause troublesome cauterization, if less is used the concentration at any one point will not be sufficient to cause the necessary coagulation for checking hemorrhage. 7. The duration of the treatment should be five minutes of the maximum current required. 8. The number of operations is necessarily dependent upon and influenced by the result to be accomplished. A severe hemorrhage can be checked, and symptomatic relief can often be accomplished by four or five séances, while a general reduction of the tumor necessitates many operations, varied, of course, according to the size and location of the growth. In some cases of large multple tumors a relief of symptoms, or symptomatic cure, must be accepted as a substitute for an actual cure. 9. The operation should be intramenstrual, if possible; if hemorrhage is continuous, however, operate during flow. The séances can occur as often as every day with the system of concentration adopted that enables one to attack different portions of the canal at succeeding treatments, or it can be given with advantage as few as once a week. 10. Since the adoption of the flexible intra-uterine electrodes and Dr. Apostoli's vaginal galvano-puncture, extra-uterine puncture should be regarded, if at all, only as a last resort. 11. Galvano-puncture needles, and the internal electrodes, should be constructed of material that is not injured by coming in contact with strong carbolic acid, or 1 to 1,000 bichloride mercury solution. All internal electrodes should be thoroughly scrubbed with a nail-brush and soap and water after each application, and allowed to remain in one or the other of these standard antiseptic solutions until they are to be employed again, when they should be washed in a weaker solution of the same before using. Before a vaginal puncture is made the vagina should be thoroughly wiped out with a 1 to 3,000 bichloride solution. 12. There is no excuse for any percentage of mortality in the proper application of this treatment. While Dr. Apostoli has had two deaths in 275 cases, he candidly admits they were due to avoidable accidents rather than to any legitimate procedure of the operation. 13. In experienced hands, and by the adoption of the present means of concentration, the most delicate and sensitive patient can receive, without experiencing any severe discomfort, all the benefits to be derived from this valuable treatment.

DISINFECTION OF THE RESPIRATORY PASSAGES WITH MYRTHOL.—The Vienna correspondent of the *New Orleans Medical and Surgical Journal* says that, hitherto, inhalations of turpentine were used for disinfecting the air-passages, or for combating putrid processes. Setting aside the frequent disagreeable after-effects which were produced by this medication, the results were also not very favorable. In spite of the inhalations, a patient affected with putrid bronchitis would infect a whole ward in a hospital. Dr. Eichhorst recommended a medicament which, taken by the mouth, was able to meet all these inconveniences, and, moreover, favorably influenced the appetite and the general condition of the patient. This drug, myrthol, had a rapid and sure effect. It was that part of the myrtle-oil which boiled at from 320° to 340° F., and which represented a quite clear fluid of an aromatic odor. It had formerly been recommended as a deodorant in the case of bronchial catarrh. According to the present recommendation it was the best medicament for rapidly and surely combating the putrescence, and for removing the bad odor of the breath and the secretions. When a gelatine capsule containing two grains of myrthol was taken, the breath distinctly smelled of myrthol after the interval of an hour, and this smell could also be perceived twenty-four hours, and even forty-eight hours, after the administration. In putrid processes much larger doses were required; in most cases two capsules were administered at the interval of two hours. There was no disgust against the drug on the part of the patients. Though myrthol proved very effectual in combating the putrid process and the bad odor connected therewith, it was quite ineffectual for preventing an infection with tubercle bacilli, as tuberculosis developed even when myrthol was used.

MORELL MACKENZIE ON HYPERTROPHY OF THE TONSILS AND ITS TREATMENT.—Chronic tonsillitis, or hypertrophy of the tonsils, proceeds from two causes. A large number of the cases are the result of a low form of inflammation occurring in childhood. The structure in childhood is very prone to become inflamed. If the tonsils are considerably enlarged, it is important to remove a portion of each. You should never speak of "cutting out the tonsils," as this sounds very alarming to the patient and his friends. Say that you mean to remove only "the diseased and enlarged portion." It is a consideration when you should do this. How much enlargement should there be before the operation is performed? First of all, the question of size is entirely relative. In a large throat the tonsils may grow to a considerable size, and the patient still do quite well. In a smaller throat this would not likely be the case. If the tonsils touch each other you can have no doubt as to the propriety of taking away a piece. If adult patients come to you with the tonsils slightly enlarged, it is an important question whether you should cut off a portion or not. If the enlargement is associated with frequent attacks of acute inflammation, you ought then to cut away a piece. There is another condition which requires a similar proceeding. When the follicles of the tonsil are much enlarged, you cannot cure it except by taking off a section, which may be not more than one-eighth of an inch thick. You thus clear away the walls of the deep follicles and get a flat instead of a "worm-eaten" surface. As to the method of operating, many surgeons do it with a bistoury, and Sir William Ferguson, a great surgeon, for whom I had the greatest admiration, used to perform it in this way, but it was terrible to see the patient struggling with the mouth half-full of blood before the operation was completed. Great surgeons will do all they can with a knife instead of what

they call a "machine." I always perform the operation, however, with "a machine," a tonsillotome. The particular form I use is a modification of Physick's. The great advantage of this is that its mechanism is quite simple, and my modification enables the handle to be fixed on either side of the blade, so that the operation may always be performed with the right hand if the operator desires. As a general rule lightness of touch is the chief desideratum in operating, but in tonsillotomy it is the reverse. Heaviness of touch is the important thing. The tonsillotome must be pressed well over the tonsil, which is also to be projected into it by pressure with the left thumb placed under the angle of the jaw. I once had a colleague who could do very little else, but he took off tonsils marvellously, and as I watched him I observed that it was this heaviness of touch that made him so successful. If you don't attend to this you will not take off nearly so much as you desire. Patients have come to me a week or a fortnight after the performance of the operation by another surgeon, saying that the tonsil had been removed but has grown again! This, of course, means that enough was not removed at the operation. It is most important to take off enough. Hemorrhage from this operation is rare, but it has occurred, and the carotid in some instances has had to be tied. I once had a serious hemorrhage to deal with some twenty-five years ago. The usual styptics, and even the cautery, failed to relieve it. At last I tried a remedy, which I have used ever since with perfect success. A chemist had informed me a short time before that a small quantity of gallic acid would prevent tannic acid dissolving. I mixed two parts of the tannic and one of the gallic in a little water, and gave the patient two teaspoonfuls, telling him to sip them slowly. The bleeding stopped almost at once. We have since used the same preparation at the Throat Hospital, and always with perfect success. The patient must be told to *swallow* the liquid, not gargle. Application with a brush will do no good. He should swallow the fluid slowly, as if it were difficult to get it down, and must on no account wash out his mouth or gargle.—*Edinburgh Medical Journal*, January, 1889.

Tubercle in the Aorta.—Dr. Dittrich reports a case of acute miliary tuberculosis in a boy, aged twelve, in which the source of general infection appeared to be the rare condition of tuberculosis of the aorta. To the posterior wall of the ascending aorta adhered some tuberculous lymphatic glands, from which the tubercle had spread into the coats of the vessel. Bacilli were found both in the glands and in the aortic wall, and it is assumed that they were disseminated through the blood-stream by direct detachment from the intima of the vessel.—*Zeitschrift für Heilkunde.*

An English Confirmation of Koch's Doctrine Regarding Cholera.—A communication of considerable importance on the subject of Asiatic cholera was made recently to the Royal Society of Edinburgh. The paper, the joint work of Dr. Neil Macleod, Edinburgh, and Mr. Walker J. Miles, F.R.C.S., was read to the Society by Dr. G. Sims Woodhead. The work was in part carried out in Shanghai and in part at the Royal College of Physicians' Laboratory, Edinburgh. It had for its object more especially the testing of Koch's statements regarding the comma bacillus. It was found possible to demonstrate the bacillus in 40 out of 44 cases of cholera, of which 30 had terminated fatally. The conclusions reached by the observers are as follows: 1. The comma bacillus of Koch is invariably present and associated with certain changes in the small intestine in cases of Asiatic cholera. 3. There is no evidence to show that it is a normal inhabitant of the human alimentary canal, and therefore no proof of the assertion that it is a result of the disease. 2. The means used to introduce the comma bacillus into, and those used to lessen the peristalsis of the small intestine of the guinea-pig, cannot be regarded as causing appearances like those of Asiatic cholera, or as causing the death of the animal, far less a mortality of over sixty per cent. 4. Pure cultivation of the comma bacillus introduced into the stomach under certain precautions described are pathogenic to the guinea-pig. 5. Injected with similar precautions, the contents of the ileum from these animals killed by injection of pure cultivation of the bacilli act in the same manner as pure cultivations of that organism. 6. The organism multiplies in the small intestine of the animal, and there are associated therewith changes similar to those in man in Asiatic cholera. 7. As there are conditions which favor the passage alive of the bacillus through the stomach of the guinea-pig, and also conditions which favor its multiplication in the small intestine of that animal, so in man there cannot be a doubt that the organism finds conditions favorable to its entrance alive, through, in all probability, the mouth and the stomach. 8. There is strong evidence, therefore, for regarding the comma bacillus of Koch as the cause of Asiatic cholera.—*The British Medical Journal.*

Is Inflammation always due to Microbes?—Professor Th. Leber, of Göttingen, has lately been engaged in some investigations having for their aim the solution of the question whether suppurative inflammation is exclusively produced by micro organisms, or whether it may also be set up by purely chemical substances (*The Lancet*). By means of injections of competely sterilized cultures of staphylococcus pyogenes aureus into the anterior chamber of the eyes of rabbits, he was able to induce intense suppurative inflammation. This, however, differed from similar inflammation produced by living staphylococci, inasmuch as it showed no disposition to spread; and even when the local appearances were of a very severe nature the morbid process rapidly came to an end. From staphylococcus cultures different chemical crystallized substances were obtained, which were shown by their reactions not to be identical with the ptomaïne obtained by Brieger from staphylococcus cultures, and which he, in consequence of its property of setting up suppurative keratitis, denominated "phlogosin." Besides, Professor Leber was able, by means of his investigations, to show that when suppuration was set up the pus-corpuscles make their way in a centripetal manner toward the spot where the inflammatory stimulus exists. He found that capillary tubes containing a small quantity of a substance capable of inducing inflammation when introduced into the anterior chamber of the eye became filled after a time with pus, while no pus at all could be detected in the eye itself. Professor Leber considers this attraction of leucocytes by chemical substances as analogous to the attractive influence of certain chemical substances in vegetable cells which has already been observed, and which has received the name of "chemo-tactical action." Finally, Professor Leber finds that in suppurative inflammation fibrin and the tissues become dissolved by means of leucocytes; for example, pieces of cornea impregnated with sterilized staphylococcus culture, when introduced into the anterior chamber of the eye, became rapidly dissolved. It was found, moreover, that pus, when free from bacteria, enjoys the property of causing a local liquefaction of nutritive gelatine. Professor Leber recognizes in these properties of leucocytes (their ability to absorb foreign bodies and to dissolve fibrin and tissues) a valuable defensive arrangement which tends to shield the organism against external injuries. He would therefore look upon inflammation as an "important process, which consists in rendering the organism obnoxious to external injurious influences."

Treatment of Gonorrhœa by Thallin.—Dr. John McCan reports a case (*Dublin Medical Journal*) of cure of gonorrhœa in three days, by the use of five per cent. sulphate of thallin bougies. Dr. McCan announces his treatment as a new one; thallin has, however, been used for some time for this trouble.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 6, 1889.

CANCER OF THE RECTUM.

THE older view, and the view of many conservative surgeons now, has been that cancer of the rectum should not be operated upon unless it was within reach of the fingers, *i.e.*, involved the lower two and a half or three inches of the rectum. This rule, however, is now far from being observed. The operations devised by Kraske and by Alexander are expressly designed to attack growths in higher parts, and these operations have been successfully employed.

It is a matter of common note, however, that although the operations upon the rectum are not now attended with so large a direct mortality as formerly, yet, as regards relief from the disease, the success has not been so great as in operations upon the open surface of the body. And the treatment of rectal cancer by the surgeon is still far from encouraging.

Dr. Hildebrand has recently presented a statistical review of the work done in this line at the Göttingen Clinic (Dr. Henry Koplik, *Annals of Surgery*, February, 1889). There were sixty-nine cases of carcinoma recti whose histories were studied. The large majority of cases of carcinoma of the rectum (fifty-four per cent.), in the clinic in question, occurred between the ages of forty and sixty years. Thirty per cent. of these cases occurred between sixty and eighty years. As regards sex, 31.7 per cent. were females. Of sixty-nine cases of carcinoma of the rectum upon which this paper is based, only two were confined to the external anal ring. Among the tumors three melanotic carcinomata were found, a rare form of growth. Most of the carcinomata of the rectum were in form of a ring-like stricture, or, again, the growth took the shape of a cuirass as in the breast. Excluding the inoperable cases, in 54 operated cases the lymphatic glands of the surrounding area were affected in 24 cases.

Of the 69 cases which came to the clinic for operation, 15 were regarded as inoperable. In all cases where the carcinoma was confined to the anal ring, extirpation of the tumor with or without the removal of the external sphincter was performed. If the mucous membrane of the rectum was compromised, extirpation of the rectum was resorted to. When the sphincters were not affected, resection of the rectum alone was resorted to. There were 2 cases of the first, 13 of the second, and 39 of the third class. The operation of Kraske was not performed in any of the cases in the Göttingen Clinic.

The rate of mortality immediately following this operation (57 cases) was thirty-five per cent. (20 cases). During the past six years the mortality only reached 14.9 per cent. against thirty per cent. of the previous six years.

Of 54 patients, 3 remained free from symptoms for more than three years, 6 for more than two years, and 8 over one year, and have, up to date, no return of disease. Of the whole number of patients, including those still living with a return of disease, at least thirty-one have lived free from symptoms for a period of three years. There are only three cases of definite cure up to the date of the statistics (ten per cent.). In the majority of cases recurrence of the disease occurs early—during the course of the first half-year after operation.

Dr. Hildebrand rightly says that the operation for carcinoma recti is dangerous to life, and rarely gives prolonged relief, while it usually and necessarily destroys the functions of the parts. Still the outlook is better than when Billroth reported 45 cases with 19 deaths, or nearly fifty per cent., instead of the present rate of ten or fifteen per cent.

THE EXPERIENCES OF MEDICAL EXAMINING BOARDS IN ALABAMA.

THE State of Alabama is one of those few joyous areas of the earth's surface that is without a medical college. It has, as an offset, however, an excellent medical journal, a well-organized State Board of Health, and a State Medical Association which has the power of appointing a Board of Censors, and County Boards of Examiners. These organizations examine, and, if proper, license applicants for the practice of physic.

That such licensing board is useful is shown in the reports of the work of these Boards, some interesting abstracts from which are given in the *Alabama Medical and Surgical Age* of recent date.

In reviewing the examination of a graduate of a Tennessee college, the Board says: "Applicant is utterly ignorant of both medicine and English, and the wonder is how any college could graduate, or board license, such a man."

The same Board says of another Tennessee graduate: "He ought to have been rejected on his spelling, though there was sufficient reason without that. His answers are not only incomplete in every case, but are often incorrect."

Of two Georgia graduates, the Board says: 1. "The applicant exhibits a lamentable ignorance of medicine." 2. "He answered almost nothing."

It says of the examination of one of the graduates of a Kentucky college: "Applicant shows the most astonishing ignorance of medicine, and, if he carries into practice some of his ideas of treatment, will materially diminish the population of his community."

A NEW FORM OF TUBERCULOSIS.

IN 1883 Malassez and Vigual discovered a peculiar form of tuberculosis not due to the special microbe described by Koch. This they called "tuberculosis zoogléique," on account of the peculiar mode of growth of the micro-organism. In 1885 Eberth discovered a "mycosis" of the guinea pig and a pseudo-tuberculosis of the rabbit, which seemed

to resemble the zoogleic tuberculosis of Malassez and Vigual.

Last year Charin and Rogers described a "pseudo-tuberculosis bacillaire."

The progressive granuloma described by Manfredi in 1888, and the "syphilis of animals" of Taguchi and Disse, appear to resemble the forms already referred to. In the last number of the *Archives de Médecine expérimentale*, MM. Grancher and Ledoux-Lebard have investigated the whole subject, and claim to identify the zoogleic tuberculosis of Malassez and Vigual with the pseudo-tuberculosis of Charin and Rogers.

Their results leave little doubt that there is an infectious microbic disease resembling in many respects miliary tuberculosis, but not due to the common tubercular bacillus of Koch. This disease has been produced in animals repeatedly. It is not unlikely that it also affects man, since the original virulent matter used by Malassez and Vigual was of human origin. Grancher and Ledoux-Lebard obtained their first cultures from garden-earth upon which gelatine cultures of Koch's bacillus had been deposited. Upon this distilled water was allowed to drip, and the filtrate was used for their first inoculations. Injected into the abdomen, these cultures caused death in four to seven days, from peritonitis with miliary granulations of the liver and spleen.

The granulations were found to consist of colonies of microbes easily stained with methyl blue. Rabbits inoculated subcutaneously died in five to six days, with tuberculosis of the liver, spleen, and lung, the colonies being deposited in masses of various sizes.

The colony-growth of these microbes was only one stage of their life. They caused local degeneration of the infiltrated parts, and then themselves disappeared. The masses are composed first of short bacilli, about one micromillimetre long, rounded at the extremities, and secondly of micrococci.

The existence of this special and virulent form of tuberculosis is at present a matter of scientific interest only. But it seems probable that man may, and does sometimes, suffer from a "tuberculosis zoogléique."

THE VALUE OF ELECTRICITY IN THERAPEUTICS.

OUR readers have doubtless read with interest the letter of Dr. R. W. Amidon in the last issue of THE RECORD, and will read, in the present issue, the letter of Dr. Starr, and the courageous criticisms they contain. They will doubtless agree also that, while a good deal of silly stuff has been written regarding the efficacy of electricity, the position of American physicians has not by any means been that of credulity. Over two years ago, in an editorial (MEDICAL RECORD, February 26, 1887), we said: "Electricity has a pain-allaying power, and relieves a number of neuralgic pains. But as to paralysis we are still in the dark. We know that after motor paths are broken in brain, or cord, or periphery, there is a process of separation which follows naturally by certain laws. But do electric currents influence this process of repair? Of this there is as yet absolutely no demonstrative evidence. Some cases seem to begin their improvement with the beginning of electrical treatment, others seem to cease their downward progress under it. But these effects are not uniform, perhaps not even the rule. . . . It is, perhaps, through the psyche that electricity acts in the majority of cases."

Electrical currents have some influence in allaying spasm and in promoting nutrition, and as a mechanical tonic. Their effects are, in the main, mechanical. The chemical and mechanical influence of the current in electrolysis, in stopping hemorrhage, in coagulating blood, and in destroying fœtal life, and the reflex effects, have also to be taken into account.

On the whole, while taking a cautious position as to the usefulness of this agent, a position of ultra-scepticism is decidedly unwise. Taken altogether, electricity is not applied as often as it might be with advantage by the general practitioner. It requires time and patience, and a little capital, for its proper use. Nine out of ten of the physicians who read this have no batteries, or those they have are out of order. The dishonest use of electro-therapeutics is something to which many may be tempted, but we cannot believe that such perversion of therapeutics is frequent. The number of persons who persuade patients and themselves that the triweekly use of a spray or caustic in the nose and throat, of iodine and glycerine tampons on the cervix uteri, of hypodermatic injections, of inhalation of medicated vapors, is necessary for recovery of health, must much exceed that of dishonest or incompetent electro-therapeutists, and the number of all classes is, we are sure, small.

THE MEDICAL FUTURE OF VOLAPÜK.

As we predicted some time ago, not a few enthusiastic students of Father Schleyer's new world-tongue are endeavoring to gain for it acceptance as the much-needed universal language of science. Several medical essays have been written in it with a view to prove its adaptability to such a purpose, and with a degree of success, its friends aver, amounting to a demonstration. We have not seen any of these essays, and cannot venture an opinion concerning them as evidence of the adaptability of Volapük to scientific uses; but we confess that we should wish to see a great many theses on a variety of subjects before being convinced that this language, in the shape in which it exists at present, can be used to describe with scientific accuracy the varied normal and pathological processes, and to fulfil all the requirements of precise medical phraseology.

One great objection is that the language is too young, that it has not attained a position of fixity, but is even yet changing. The forms of some of the letters have been changed, the pronunciation has been modified, and now it is proposed to alter the spelling, leaving out entirely certain letters which stand for vowel-sounds foreign to English ears. This is a fault common to almost all inventions, and experience is constantly pointing out defects and suggesting improvements. This is well, and, in the case of Volapük, it will doubtless result in the production of a more nearly perfect instrument for the expression of thought. But until this process is completed, the language will not commend itself to science. Besides, there is no guarantee that it will ever become fixed. It is true, there is an Academy of Volapük by which every proposed change must be approved before it can become a law, but

language laughs at authority and changes itself in spite of the will of man. This is true of the natural tongues, and is no less likely to be the case with one arbitrarily constructed.

Finally, we are not convinced that Volapük is the best of the artificial languages, although it is the one that has obtained the widest acceptance. Its inflections are simple enough, but it is a question whether it would not have been better to have had fewer of them. In this respect some of its rivals seem to be superior to it. One of these new languages, very simple in its construction and ingenious in its conception, is "Spelin," devised by Professor Bauer, of Agram. In this language the number of inflections of both verbs and substantives is reduced to a minimum, rivalling English in its poverty in this respect. It is possible that this will be found better adapted to the needs of international communication than Volapük, and then we should have two so-called world-languages. Let this process continue, and it will not be long before we shall have a dozen artificial tongues, and the object of their creation will thus be defeated.

Medicine is in need of a common tongue, but it is not likely that any artificial system will meet the want. We still have Latin, although, unfortunately, it is of little use to the present generation of physicians. But it could easily be made available for the coming generations, if only the thick-skulled instructors of youth could be persuaded to teach it in a more rational manner, so that it might be again a living tongue, and not a mere framework on which to hang a string of dry grammatical rules.

News of the Week.

EXAMINATIONS FOR VACANCIES IN THE MEDICAL CORPS OF THE ARMY.—An Army Medical Board has been ordered to convene in New York City on the coming 1st of May. There are at present seven vacancies in the Medical Corps, to which one more will be added in July by the retirement of a medical officer, making eight appointments which are to be recommended by this Board.

THE PERENNIAL OFFICE THIEF is here again in the person of a woman clad in a rusty black dress, with fur-lined satin dolman somewhat the worse for wear. If she is so unfortunate as to call when the doctor is at home, she generally makes an appointment with him to see a woman who is in the family way, or sends him off to a bogus address to visit a sick child.

THE SAMOAN ISLANDS, writes Dr. Vanderbeck in the *Medical and Surgical Reporter*, are the natural habitat of elephantiasis. It is endemic here. The inhabitants of Tutuila and the most eastward of the five islands constituting the group suffer most with it. Strange to say, it is uncommon in other groups quite near, as, for instance, in the Tongatabu, Society, Friendly, and Fiji Islands. I can find no satisfactory explanation for this fact. The natives say it is due to being in the sea-water so much; but Samoans are not exposed this way more than the other islanders. Some of the cases now in Leone are sights indeed. One tumor weighs seventy-six pounds, another forty-eight pounds, besides the frightful enlargement of the legs and arms. A woman has a labial tumor of this kind weighing fifty six pounds. Many of the cases are among aged people, who have been affected for very many years. The natives occasionally operate on each other, using either a razor or a prepared bamboo stick, which is said to cut equally well.

DR. A. M. PHELPS, of this city, was recently elected to the chair of surgery in the University of Vermont. The course in surgery commences May 15th.

MEDICAL COLLEGE COMMENCEMENTS.—The Louisville Medical College has graduated one hundred and three students; the Philadelphia Woman's Medical College, thirty-six.

ANOTHER DISCOVERER OF A CANCER BACILLUS has arisen in the person of Professor Platon I. Kübasoff, of Moscow, who reports the discovery of a pathogenic rod-shaped organism whose inoculated cultures cause cancer in lower animals.

PROFESSOR VIRCHOW is at present much occupied in revising his great work on Cellular Pathology.

A NEW MEDICAL COLLEGE is said to have been organized at Asheville, N. C., with the hyper-geographical title of the "Western North Carolina Medical College."

THE MEDICAL PROFESSION will be pleased and astonished over the news that the galvanic current is useful in facial paralysis. This important discovery has been announced as news, and editorially endorsed, by a daily paper of this city, which has lately been making some unique excursions into medical journalism.

THE TREATMENT OF LOCOMOTOR ATAXIA BY SUSPENSION has been tried in this city for several weeks, at the clinic for nervous diseases of the Post-Graduate School, under the direction of Dr. C. L. Dana. The results, so far, we learn, have been only moderately encouraging.

TREPHINING THE PELVIS FOR PSOAS ABSCESS is a recent novelty in surgery, introduced by Dr. Michel Gangolphe (*Revue de Chirurgie*). He has operated upon two cases, one ending fatally and one in a cure.

THE HOAGLAND LABORATORY OF BROOKLYN has received a check for $10,000 from Dr. Daniel Ayres.

A CASE OF STRICTURE OF THE ŒSOPHAGUS, cured by electrolysis, has been recently reported to the Académie de Médecine by M. Fort.

BEQUESTS TO MEDICAL CHARITIES.—In the will of the late Isaiah V. Williamson, of Philadelphia, who died March 7, 1889, leaving an estate valued at about ten millions of dollars, the following bequests were made: To the Pennsylvania Hospital $100,000; $50,000 each to the Episcopal Hospital, the University of Pennsylvania, and the University Hospital; $40,000 each to the Children's Hospital, the Women's Hospital, the Orthopedic Hospital, and the Woman's Medical College.

BILL FOR ADULTERATION OF FOOD DEFEATED.—The House Judiciary General Committee of the Pennsylvania Legislature decided, on March 8th, to report negatively the bill advocated by the Society to Prevent Food Adulteration. The bill was aimed to prohibit harmful and deceptive, and regulate harmless and necessary, adulteration of food and drugs. It was thought that the present laws were sufficient.

ORGANIZATION OF A GERMAN DERMATOLOGICAL ASSOCIATION.—At a recent meeting, in which sixty-nine dermatologists from Germany, Austria, and other countries took part, it was resolved to found a German Dermatological Society, which should hold a congress every year in Whitsun-week. The following committee was appointed to make arrangements for holding the first congress this year at Prague: Professor F. J. Pick (Prague), President; Professor A. Neisser (Breslau), Secretary; Professor E. Lipp (Gratz), Treasurer; Professors J. Caspary (Königsberg), Doutrelepont (Bonn), Kaposi (Vienna), Lewin (Berlin), I. Neumann (Vienna).

A NEW HYPNOTIC, URALIUM.—Signor Gustavo Poppi, a medical student of Bologna, recently described to the Medico-Chirurgical Society of that city the effects of a new hypnotic, which he proposes to call "uralium." This substance is produced by the combination of chloral hydrate with urethan. From experiments on animals and on the human subject, Signor Poppi concludes that uralium induces sleep more quickly and more certainly than any other known hypnotic. He says that it causes no alteration of the blood-pressure, nor bad effects of any kind.—*British Medical Journal.*

RECEPTION TO PROFESSOR WILLIAM OSLER, M.D.—The Society of the Alumni of Bellevue Hospital gave a reception at the Cambridge Fifth Avenue and Thirty-third Street, to Professor William Osler, on Wednesday evening last, after the delivery of his lecture before that body. A large number o representative medical gentlemen were the guests of the evening, and the occasion will long be remembered by all who were present as one of the most enjoyable of the season. A magnificent supper, with the usual bibitory accessories, was furnished by Mr. Reich.

AN INTERNATIONAL CONGRESS OF THERAPEUTICS AND MATERIA MEDICA will be held in Paris, under the presidency of M. Moutard-Martin, August 1 to 5, 1889. The following subjects are announced for discussion: "The Analgesic Antithermic Remedies;" "The Antiseptics Suitable for the Destruction of each Species of Pathogenic Micro-organisms;" "Heart Tonics;" "New Drugs of Vegetable Origin recently Introduced into Therapeutics;" "The Unification of Weights and Measures Employed in Prescription Writing; The Utility of an International Pharmacopœia." Those desiring to read papers at the Congress are requested to notify the Secretary, Dr. Bardet, 119 *bis* Rue Notre-Dame-des-Champs, Paris, before May 15th.

BEEF-EATING CANCERS.—An editorial in the *New York Medical Journal* refers to the fact that, in certain parts of the West there is a belief that cancers have a fondness for beefsteak, and that raw beef applied directly upon the tumor is consumed. A correspondent of the *Journal* writes from New Brunswick, Canada; "I find the impression prevailing among a certain class in this neighborhood that the application of raw beef to a cancerous ulcer will restrain the ravages of the disease, and am aware of one case of scirrhus of the breast in a lady, a doctor's widow, in which it was used with alleged benefit. This was before my residence here, therefore I cannot give particulars of the case, further than that the cancer is stated to have 'eaten' *five pounds of steak daily.*"

Obituary.

JOHN SWINBURNE, M.D.,

ALBANY, N. Y.

THE death of Dr. John Swinburne, on March 28th, removes a unique and prominent figure in the medical and political circles of the State. Dr. Swinburne was a farmer's son, having been born at Denmark, Lewis County, N. Y., in 1821, where he spent the early years of his life, his boyhood days being devoted to helping his father till the soil and working in the country store. After a two years' course of study at Fairfield Academy he determined to become a physician, and in 1842 he went to the Albany Academy, where he applied himself earnestly to the study of medicine. Four years later he was graduated at the head of his class, and his knowledge of anatomy was so thorough that he was at once appointed demonstrator in the institution from which he had just been graduated. After four years spent in this way he opened an office in Albany and began to practise.

During the War of the Rebellion Dr. Swinburne served as a surgeon, and did much good work in extending the hospital service. Many a soldier has Dr. Swinburne to thank for saving an arm or a leg which otherwise would have been sacrificed to the amputating knife. Upon his return from the field, in 1864, Governor Seymour, in recognition of his valuable services, appointed him Health Officer of the port of New York, an office which he filled with ability and success for six years. At the expiration of that time he went abroad, and served during the Franco-German War, being in charge of the American Ambulance Corps at the siege of Paris. For this service he was decorated with the Cross of the Legion of Honor. In 1873 he returned to Albany and resumed practice, establishing a free dispensary.

Dr. Swinburne was elected Mayor of Albany in 1882. In 1884 he ran for Congress, and was elected by a large majority, but two years later he was defeated, after a hard-fought contest. The autopsy showed that Dr. Swinburne's death resulted from cancer of the stomach.

R. P. HOWARD, M.D.,

MONTREAL, CANADA.

DR. R. P. HOWARD, dean of McGill Medical Faculty at Montreal, died on March 28th, of pneumonia. Dr. Howard studied medicine in McGill University and in Great Britain and France. In 1849 he returned from Europe and commenced the general practice of medicine, and soon became the first physician in Montreal. In 1856 he was appointed Professor of Clinical Medicine in McGill University, and in 1860, upon the death of Dr. Holmes, succeeded to the Chair of Theory and Practice of Medicine in the same institution. About three years ago the degree of LL.D., *honoris causa*, was conferred upon him by the university in which he had been a professor for thirty-four years.

Dr. Howard was President of the Canada Medical Association, President of the College of Physicians and Surgeons of Quebec, President of the Medico-Chirurgical Society of Montreal, and Vice-President of the Association of American Physicians. In 1887, on the occasion of the centennial of the College of Physicians of Philadelphia, he was made Fellow of that body. For twenty-two years he was one of the attending physicians and surgeons of the Montreal General Hospital, and was the secretary of that institution for thirty-three years.

Dr. Howard contributed largely to medical literature. He wrote upon pneumonia, phthisis, heart disease, and anæmia, and his works upon these subjects made him a recognized authority in the profession. In 1885 he wrote a series of articles on rheumatism and allied subjects. As a teacher Dr. Howard was painstaking and industrious, and was considered a model lecturer.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, March 25, 1889.

ALEXANDER S. HUNTER, M.D., PRESIDENT, IN THE CHAIR.

DR. AUGUST SEIBERT read a paper entitled

THE ETIOLOGY OF FIBRINOUS PNEUMONIA.

Hardly any difference of opinion existed in former times regarding the etiology of pneumonia, as this disease was supposed to be the most conspicuous and evident example of inflammation brought about directly by exposure to cold. Only within the last twenty years, after the attention of medical men had been drawn to repeated observations of endemics and epidemics of pneumonia, and since the pathological changes during other processes could be traced to the division and growth of infectious material brought into the human body, and since the old ideas on inflammation and the formation of pus were modified by antisepsis, did prominent observers come forth with the theory that fibrinous pneumonia also was but an infectious disease. The discovery of that variety of pneumonia characterized by its tendency to wander from one part of the lung to another apparently started speculation on this question. Migratory pneumonia was first described by Weigand and Waldenberg, in 1870. The so-called one-day pneumonia, characterized by a critical fall of temperature twenty-four hours after the initial chill, while dulness, bronchial respiration, and rusty sputa could be observed a few days longer, was first described by Leube, in 1877, followed later by Weil and others. If all known symptoms but the elevation of temperature remained, then certainly this phenomenon did not coincide any more with the prevalent idea regarding active inflammation. Gradually statistical reports came forth concerning soldiers in the field and in barracks, Arctic expeditions, convents, boarding-schools, etc., which went to show that persons leading an out-of-door life, often exposed to bad weather, were in less danger of pneumonia than those who lived indoors. They also showed that the tendency to get pneumonia was in exact proportion to the time spent in close rooms. Mr. Budderbeck, druggist, and one of the survivors of the Greely expedition, told the author that in spite of extreme suffering from hunger and cold, not one of their number in all that time had a cough, not to speak of pneumonia.

Dr. Seibert cited numerous statistics of epidemics or endemics of pneumonia among persons confined more or less in the same rooms, which rooms were warm, moist, and filthy. It was but natural that these manifold reports, mostly dated within the last twenty years, should stimulate some to experiments, others to statistical comparisons. Heidenhain attempted to produce pneumonia by forcing cold air into the lungs of animals, and failed, and others failed after him. A number tried to find the peculiar weather-influence present in determining the frequency of pneumonia, and failed; but Poet, Leufft, Seitz, Baker, and Seibert were more successful, and their results coincided very much, though differing in explanation.

In his first report on an investigation regarding pneumonia and the weather, published in 1882, Dr. Seibert was able to prove that catarrh of the air-passages and pneumonia showed similar lines of frequency, meaning that when pneumonia was frequent catarrh was also frequent, and *vice versa*. This view had since come to be generally admitted. In a collective investigation regarding pneumonia and the weather, carried on by the Committee on Hygiene of the County Society, 1884–85, forty-four practitioners of New York and Brooklyn, and four hospitals, took part, and gave the following results: The origination of fibrinous pneumonia is greatly favored by certain meteorological conditions, thus explaining the difference in its frequency during the twelve months of the year. Low and falling temperature, high and rising humidity, and high winds were each capable alone of exercising this influence. If two of these weather conditions were found together, there were more cases of pneumonia than when one alone was present. If the three—cold, moisture, and high winds—were present, the frequency of pneumonia was great. Existing catarrh predisposed to fibrinous pneumonia.

In all his cases of endocarditis complicating pneumonia, Weichelbaum was able to cultivate Friedländer's pneumococcus from the pathological deposits on the endocardium. Emil Senger also found this organism in all fatal cases of pneumonia in the lungs, as well as in the complications (meningitis, pleurisy, endocarditis, nephritis, and pericarditis).

After carefully reading the article of Dr. Sternberg in the last two numbers of THE MEDICAL RECORD he was satisfied that Fränkel's coccus, described by Dr. Sternberg as "Micrococcus Pasteuri," would probably cause the more frequent form of pneumonia known as the sthenic variety, while the pneumococcus of Friedländer was the usual agent for producing the asthenic, bilious, or typhoid variety. But to his mind the most important investigations regarding the germ origin of pneumonia were those of Rudolph Emmerich. In the State prison at Amber, where an endemic of pneumonia had attacked 161, and killed 46, out of a total of 1,150 prisoners, Emmerich found Friedländer's coccus between the ceilings and below the floors of the sleeping apartments in great quantities, embedded in very moist *débris* which had been used to fill up the spaces. Mice infected by injections into the lung-tissue all died, and artificial pneumonia also occurred when they inhaled the microbe.

Secondary infiltrations in wandering pneumonia were to be explained, not by inflammation passing along by continuation of surface, but by the presence of an infectious material. Central pneumonia, and cases lasting but one or two days, also spoke for infection. Endemics and epidemics proved not alone that pneumonia was caused by specific poisons, but also that the germs were apt to thrive and grow in certain localities, at certain times, and under certain conditions, the important ones of which he had already mentioned. Whether or not pneumonia was contagious, so that the germ of the disease might pass directly from the patient to the attendant, as in measles and scarlatina, had not yet been settled. If at all contagious, it certainly was only to a very mild degree. Friedländer's pneumococcus appeared to thrive best in warm, moist, dirty rooms and houses. This statement was in accord with observed epidemics.

Pneumonia was found oftener in old and very young persons than in the middle-aged. Children under two years of age were attacked oftener than older ones. The explanation was that old people and children were less out of doors.

Pneumonia not only frequently attacked persons suffering from bronchial affections, it was also found complicating those diseases in which the pulmonary mucous membrane was usually in a state of congestion and hyperæmia, as typhoid, measles, and pertussis. On the other hand, pneumonia was not often seen complicating scarlatina, diphtheria, and meningitis. We were forced to conclude that the catarrh of the bronchi being absent in the one class of diseases, the opening in the mucous membrane necessary for the admission of the pneumococcus poison was wanting, which for its growth and multiplication was as essential as was a lesion of the skin for the origination of erysipelas.

DR. FRANCIS DELAFIELD opened the discussion. There seemed to be no department of disease concerning which our knowledge was still so uncertain as it was regarding causation. If we had made any advances in this direction it was due to the fact that we no longer accepted general statements concerning the causation of any disease, but looked more and more for exact data and exact work.

Until we got this we were becoming contented to acknowledge how little we knew of the real cause of disease. While this was true of many affections, it was particularly true of pneumonia. Although pneumonia had been known to physicians for many years, yet we could hardly say that any definite attempt at the solution of its causation had amounted to anything until within the last few years, and even yet the work done was so small in comparison with what was to be done that he thought no wise man would care to speak with any certainty as to its causation. We did not yet know, but the knowledge was on its way to us.

We knew in a general way that pneumonia seemed to belong to the class of infections inflammations; inflammations in which the inflammatory process was always accompanied with the production and the growth of a pathogenic bacteria. Such infectious inflammations required three factors for their development—a pathogenic bacterium, some exciting cause for the inflammation, and susceptibility.

A curious thing about such inflammations seemed to be that at different times and in different places, the one or the other of these three factors took the prominent part. Sometimes the bacteria took the prominent share, as the causative factor, in others the surroundings, and in others the susceptibility of the person.

In addition to this it must be admitted that the bacteriology of pneumonia was in its infancy. We were only just beginning to know about it. As far as we had advanced it seemed tolerably evident that more than one form of bacteria was capable of causing inflammation of the lung. We had descriptions of certain different forms of bacteria which had been observed in pneumonia, but as to general classification we were still altogether in doubt. Then it must have been noticed by all, that in pneumonia, as in some other infectious inflammations, there was a remarkable difference in patients suffering from the affection, as concerned the constitutional symptoms. Some patients behaved throughout as if they merely had a local inflammation of more or less severity, while others appeared like patients suffering from general infection in addition to their local disease. This was one of the most characteristic factors of the disease.

Dr. L. Emmet Holt had little to add. What was needed was more facts. There were plenty of theories. One thing which had impressed him more and more in this infectious disease was the difference in predisposition in different patients. This was most notable, perhaps, in children. This was also true of other affections, and was noticeable even in vaccination.

He thought fibrinous pneumonia was a rare complication of whooping-cough and measles in children. He had made many autopsies on children dying of pneumonia complicating whooping-cough, and he had yet to see fibrinous pneumonia at the dead-house. Diphtheria, on the other hand, was often complicated by broncho-pneumonia, though not by fibrinous pneumonia. He thought Dr. Seibert had stated too strongly that fibrinous pneumonia was very much more common during the first two years of life, while broncho-pneumonia was common in later childhood. Proportionally, the number of cases of fibrinous pneumonia was much larger, according to his observation, during the third, fourth, and fifth years.

In dispensary practice he had noticed great frequency of pneumonia among tenement-house children, those who never got fresh air, which went to show that it was a house disease. Abortive pneumonia was similar to what was seen in other diseases, as scarlatina, where the rash might last but half a day, and the temperature remain below 100° F.

Dr. Andrew F. Currier emphasized the statement made by Dr. Delafield, that there were other factors besides an infecting germ which should enter into our consideration of the cause of infectious diseases. This being true, the general practitioner, who had to rely upon the investigations of those engaged in special work for data on which to base an opinion as to causation, should not overlook the landmarks given them by careful observers of the past.

Dr. Messenger spoke of predisposing causes of pneumonia, and said he had found it more likely to occur in those of the rheumatic tendency. But, as Dr. Delafield had said, we did not know much about it after all.

Dr. Seibert, in closing the discussion, said he by no means considered all work necessary for a clear understanding regarding the etiology of pneumonia finished. Yet he thought that the facts and reports given in his paper were of great value, as they were undoubtedly correct. The frequency of fibrinous pneumonia in infancy could not be determined on the post-mortem table, as it was well known that this disease in the great majority of cases among children did not end fatally.

That acute rheumatism appeared to have some relation to pneumonia was undoubtedly true, as the speaker considered inflammatory rheumatism also to be an infectious trouble, also originating chiefly during winter and spring, and in its worst forms in moist, filthy apartments (basements).

The main point in the present status of our knowledge centred in the fact that we consider fibrinous pneumonia as an infectious disease, the germs of which thrive and multiply in the filth and dirt of dwellings. It is immaterial whether Friedländer's, Fränkel's, or Sternberg's coccus caused the disease, as long as we recognize the fact that when infection takes place it occurs in-doors, not in the open air. If, then, we accept this, then we can work on to accomplish in internal medicine what the surgeons have long since been doing in operative medicine: prevent infection by cleanliness and antisepsis, for the great future of internal medicine is in the prevention of disease.

Dr. Holt corrected an erroneous impression which Dr. Seibert had received from his remarks on fibrinous pneumonia at post-mortem examinations. He had seen but one case of fibrinous pneumonia at the dead-house. What he meant to say was, that pneumonia was frequent in measles, and the form shown to be present at the post-mortem table was broncho-pneumonia, not fibrinous pneumonia.

THE CASE OF BROWN VERSUS PURDY.

Dr. Daniel Lewis read the report of the committee which had in charge the appeal of this case. The reversal of the decision, giving the plaintiff Brown five hundred dollars, had been sustained by the Court of Appeals. The expenses had been only thirty-one per cent. of the sum subscribed by various members of the County Society. The remaining sixty-nine per cent. would be returned. Dr. Lewis said that in view of this decision it was not likely physicians would be troubled by such prosecutions in the future. A vote of thanks was extended the committee, and the substance of the report ordered spread on the minutes.

Soya Bread in Diabetes.—Dr. Lecerf has used bread made from Soya flour in a number of cases of diabetes and regards it as a valuable addition to the dietary in this disease, and as far superior to gluten bread (*Journal de Médecine de Paris*, December 9, 1888). *Soya hispida* is a leguminous plant growing in Japan and the far East, the grain of which is used by the natives in the preparation of sauces and to make a sort of vegetable cheese. It contains a large proportion of fat, which takes the place in great measure of the starch in other grains. The bread made from it resembles rye-bread, has an agreeable taste, and is quite digestible. It has a tendency to cause diarrhœa at first, but patients soon become accustomed to its use and can then take it without any inconvenience.

It is said that the people of India are able to perceive three hundred different shades of color not perceptible to European eyes.—*Medical Times.*

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 21, 1889.

ALFRED L. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

ON THE PLACE OF ELECTRICITY IN THERAPEUTICS.

DIFFERENT phases of this subject were discussed by several members. First, DR. M. ALLEN STARR read a paper entitled,

THE PHYSICS AND PHYSIOLOGICAL ACTIONS OF ELECTRICITY; FACTS VERSUS THEORY.

Electricity, he said, had been introduced into therapeutics over one hundred years ago, and since then had at different times met with varying degrees of favor. Twenty years ago its use in the treatment of nervous diseases was thoroughly established, yet recent books generally disregarded the advances which had been made in the physics of the agent and failed to reflect modern views of its usefulness. Dr. Starr thought the term "current" was partly responsible for the failure of physicians to correctly understand electricity and estimate its real value in therapeutics. The sooner it came to be realized that electricity, like heat and light, was merely a form of activity in matter, and the sooner the term electrical current gave place to the more accurate expression, state of electripcation, the sooner the mystery surrounding the agent would disappear. A new molecular state was produced by electricity, but nothing was added to or subtracted from the body itself. Between the two poles on the body this molecular state was more intense than elsewhere. The term "dosage" should not be employed, as it would be as misleading as the term "current."

Static or frictional electricity, voltaic electricity or galvanism, and induced electricity or faradism—all these forms were really the same mode of energy displayed under varying conditions. It seemed strange how much credence was still given static electricity in therapeutics, for its action was limited exclusively to the surface of the body charged; it did not penetrate the skin, could not permanently charge the body, and could produce a curative effect only as a surface-irritant or by reflex action, which effect could be obtained equally well by faradism, or by massage, lomi-lomi, whipping with twigs, etc.

A more permanent electrical condition could be obtained through galvanism, yet, when definite results from this form of electricity were spoken of, he thought there must be few physicians who would contend for a moment that there was any such certainty regarding therapeutic effects on the body as there was regarding drugs. Opium, for instance, would quiet pain; but was there any therapeutic effect equally definite from electricity? He thought not.

As far as the effects of galvanism were known they might be classed under three distinct heads: Catalytic, cataphoric, and electro-tonic. A strong current passing through the body produced catalytic, or disintegrating effects, raising blisters, at one pole containing an acid fluid, at the other an alkaline. In a few instances this effect could be made use of with advantage, as in the removal of hairs, but in the case of strictures good authority pronounced it a failure, and in the removal of tumors its effects, being less definite and less satisfactory, caused it to give place to other surgical procedures.

The use of mild, non-destructive currents had been advocated by some as an aid to nutrition. The only scientific observation which he had seen in this direction was that of Dr. Thatcher in a case of paresis of the upper extremities, where it was shown that under the use of galvanism one arm made almost double the progress of its fellow toward recovery. Under faradism no gain was perceptible, while under massage there was positive loss. It was undoubtedly the catalytic effect which was responsible for the nutritive change, and it was undoubtedly due to this action that benefit, if any were obtained at all, resulted from the use of galvanism in nervous diseases.

He had never seen a case of organic disease of the brain or spinal cord which he could consider cured by electricity. Such cases sometimes improved under treatment for a time, and then grew worse in spite of treatment, while others did not improve at all. In this respect his experience coincided essentially with that of Gowers. The only use of electricity in such diseases was found in its power to promote the nutrition and strength of paralysed muscles. It did not affect the pathological state in the cerebral organs.

Another question related to the amount of influence produced by electricity upon the deeper tissues, such as the brain and cord. The power in different tissues of conducting electricity was variable; to follow the charts in this respect was to be deceived. But a small fraction of the current reached the deep nerve-structures as compared with the amount applied to the surface. By applying the current to the surface of the body and making accurate electrical measurements in the brain when exposed by a surgical procedure, something definite, he thought, might be learned in this regard.

It was not improbable that favorable nutritive effects were induced by this agent through increasing circulation and causing more rapid chemical changes in certain paralyses, as lead palsy, yet he had not positive knowledge that the duration of lead palsy was shortened by the use of electricity. In neuralgias this therapeutic agent was of considerable value, but often disappointed expectations.

The power of electricity to promote osmosis was well proven. It had been used some of late to produce local anæsthesia and quiet pain, cocaine and aconitia being applied directly to the nerves. Medicated baths might be used on this plan, but they could not at present be commended, as the dose employed was wholly uncertain.

The faradic current was always electro-tonic, never catalytic or cataphoric, in its action. It was of great use in exciting the respective tissues to activity by producing changes in the electro-tonic state. The author closed with the following statements: 1. Static electricity offered nothing more than the interrupted galvanic current, and failed to furnish those effects which were most desirable in the treatment of disease. 2. The constant galvanic current could produce chemical changes which aided nutrition or destroyed tissue according to the strength employed. 3. The constant galvanic current could transfer medicines into the body from without. 4. The interrupted galvanic current or faradic current could excite various organs to functional activity. 5. It was questionable whether the pathological state causing organic diseases could be in any way influenced by electricity. 6. If functional diseases were benefited, it was in an uncertain manner, and the physiological indications for the agent were as yet uncertain. As a therapeutic agent its use was somewhat limited, and careful observation and analysis were required to establish its sphere.

After the constant use of electrical treatment for the past ten years, the author said he had been disappointed in the results obtained, and he could not ascribe this to any defect in application, as he used the best method with careful measurements.

DR. L. C. GRAY then read a paper entitled,

THE EFFECTS OF ELECTRICITY ON CENTRAL NERVOUS DISEASES.

First, however, he made some remarks on the paper of Dr. Starr, which, he said, contained some statements which had rather startled him. He would reply to the question, Could electricity be given as definitely for a definite purpose as opium? in the affirmative. There were certain affections which he would undertake to relieve with electricity with as much certainty as other affections with opium or quinine. Neither opium nor quinine was infallible, nor was electricity. He would undertake by electricity to relieve certain neuroses, and benefit as positively as any drug could do certain symptoms in cerebral disease, but not to cure the organic disease. He did not

know that anything more positive could be said of the effects of opium or quinine, or any other drug. But there was a great deal in the way electricity was used, and at the opening of his paper he briefly stated the latest approved manner of using it.

The reader based his deductions regarding the value of electricity in therapeutics on sixteen years' experience with it. For convenience he divided the diseases of the brain into the insanities and gross cerebral lesions. From the insanities he excluded in this connection the very chronic and incurable forms. But subacute mania, melancholia, the insanity of doubt, and functional insanities could all usually be benefited by electricity, but only in the period of convalescence, not in the acute stage.

Of the gross cerebral diseases it might be said that it was useless to administer electricity in brain tumors, meningitis of traumatic, epidemic, or aural origin, or in facial hemiatrophy. It was a useful adjuvant in intracranial syphilis in the early stage of headache and insomnia, and sometimes in the later stage following hemiplegia. Hemiplegia due to neoplasm and meningitis was omitted from treatable cases. If the molecular changes induced by chronic endarteritis of middle age, or of nephritis, or by emboli were such as not to lead to a fatal issue in case of hemiplegia, they could usually be favorably influenced by electricity when the primary symptoms of shock had thoroughly passed off. Meningitis of traumatic origin, if slight, might be benefited by electricity, and if hemiplegia of vascular origin were not followed by contracture it could also usually be thus benefited. Tic douloureux was uncertain in its response to electricity.

Dr. Gray said he had no faith in static electricity. The two currents which would answer every purpose of the physician were the galvanic and faradic. Speaking in a general way, the insanities required only electrical treatment directed to the intracranial contents, and this was best done with the galvanic current. Gross cerebral diseases produced two classes of symptoms: Those which were entirely cerebral, and those which were both cerebral and peripheral. In the former class galvanism addressed to the cranial contents would usually answer every purpose, while in the latter it might be better to address galvanism to the intracranial contents, and faradism to the affected peripheral structures. The method of applying the currents in the several cases was described.

He said the question as to which pole should be employed in the case of faradism, or as to whether an ascending or descending current should be used, had been a very puzzling one to him. He was perfectly well aware that there was a difference between the chemical effects of the negative and positive pole, that there was a physiological difference upon which had been based the prognostic use of electricity, and also that every patient could distinguish the positive from the negative pole by the sensation; yet, in spite of all these indubitable differences between the two poles, he had never been able to satisfy himself that there was a therapeutic difference between them. Reasoning from *a priori* considerations, the textbooks told us that the positive pole was sedative and the negative pole stimulant, yet he had over and over again unavailingly endeavored to obtain indications for the use of the positive or negative pole in a given disease. The only rule which he could lay down was this: Where one pole did not agree, try the other; and if that did not agree, stop using electricity.

THE EFFECTS OF ELECTRICITY IN SPINAL-CORD DISEASES.

Dr. W. R. Birdsall read a paper on this subject. He admitted as truthful the doleful picture of the therapeutic effects of electricity in spinal-cord diseases, which Dr. Starr had drawn, only in so far as it applied to other remedies as well. Too much should not be expected of this agent in a class of diseases which were incurable. Like Dr. Starr, he had never seen a case of organic disease of the spinal cord cured by electricity; but he went further, and stated that he had never seen such a case cured by any single therapeutic agent whatever. But for the relief of symptoms he had seen electricity serve a more useful purpose than any other. And, as a rule, in this class of affections we attempted only to follow symptomatic indications, as the relief of pain, anæsthesia, spasm, paralysis, trophic changes, symptoms which were the result of a variety of diseases of the spinal cord and its membranes. It might be laid down as a rule that in acute inflammatory affections of the cord electricity was not beneficial, and might prove injurious. Its use should be restricted to non-inflammatory affections. This led to the question, What were the effects produced by electricity? It was essentially a stimulant, an exciter of living tissues.

In therapeutic application we could not expect to find the distinctive effects of the cathode and anode as observed when electricity was applied to an isolated nerve. We did, however, know the effects of these agents on nerve-tissue, even more definitely, he thought, than we knew the effects of drugs. He believed a large part of the beneficial effects of electricity were indirect or reflex. The very fact that one could produce a strong muscular contraction, or sensory impression, by static electricity showed that it was an agent of decided force. In this connection the question of influencing the spinal cord or deeper structures naturally arose. He agreed with Dr. Starr that, by the ordinary method of applying the electrode to the back, a very feeble impulse was obtained in the cord, yet he believed that the cord could be excited in that way. All the tissues between the two electrodes which had a resistance not greater than that which the electro-motor force would overcome transmitted the current according to the ratios of their resistance. He believed, however, that the main benefit obtained from electricity in spinal-cord diseases was due to the peripheral impression.

The chief benefit which he had observed was in enabling the patient to recover more rapidly from partial paralysis than he would without electricity. Also in infantile paralysis improvement had taken place under galvanism in cases which had previously been at a stand-still. Paralysis from myelitis, also facial paralysis, and lead palsy had improved under electricity, chiefly galvanism.

Dr. A. D. Rockwell then read a paper on

THE EFFECTS OF ELECTRICITY IN PERIPHERAL NERVE-LESIONS.

The cases considered were those of functional troubles, among the more important of which was facial paralysis. He had seen many such cases hastened toward a cure by electrical treatment. In illustration of the form of current called for in given cases, he cited one in which the physician who first saw the patient, suffering from facial paralysis, applied faradic electricity without appreciable benefit. When brought to Dr. Rockwell, he made use of galvanism and the patient recovered. Here the intramuscular nerves were paralyzed in the beginning and failed to react to faradism, while the muscular fibres being still intact, they responded to galvanism. Faradism exerted its greatest influence upon the intramuscular nerves, and galvanism upon the muscular fibres. Dr. Rockwell had obtained much benefit from electricity in diphtheritic paralysis.

Dr. E. D. Fisher read a paper on

THE EFFECTS OF ELECTRICITY IN FUNCTIONAL NERVE-AFFECTIONS.

The reader alluded briefly to the theory of the action of the agent in these cases, but said he quite agreed with Erb, who had expressed the view that we might as well do away with the bromides and arsenic in functional nervous diseases because we did not understand the theory of their action as to abandon electricity because of our ignorance of the laws underlying its influence. Undoubtedly galvanism was more important as a remedial

agent in functional nervous diseases than was static or faradic electricity; yet, with regard to static electricity, he would say that in his opinion it should not be so positively discarded as it had been by Dr. Starr. Especially in neurasthenic cases did it have a stimulating and pleasing effect. It was in functional diseases, with error in nutrition, and not organic troubles, that static electricity found its field of usefulness.

ELECTRICITY IN THE TREATMENT OF UTERINE FIBROMA.

DR. PUTNAM-JACOBI discussed this subject from the statistical point of view. The statistics were very few, considering that Apostoli called attention to the treatment as long as four years ago. Many criticisms of the method had been made, mostly by English surgeons. Keith had been favorably impressed by it, and she had hoped to find definite statistics of his results, but he had only stated in a general way that he had made twelve hundred applications to over one hundred patients, the majority of whom were suffering from uterine fibroids; that they were commonly relieved. He also stated that a number who had come to have an operation performed received, instead, applications of electricity, and went home without an operation, the tumor being reduced in size. It was not unusual to see it stated by the few who had published their experience with this method of treatment that the patients were relieved of symptoms, and that the tumor was reduced somewhat in size, but many of the observations were imperfect, the treatment being applied but once or a few times, and the cases not followed up.

DR. GEORGE W. JACOBY thought the entire subject of electricity in therapeutics was one regarding which it was difficult to arrive at positive data; that those discussing it must take an empirical stand, either for or against, for the simple reason that one was dealing with physiological effects of which he knew but little. The one said the action was catalytic, the other that it was electro-tonic, and a third that it was reflex. In other words, they knew not what was occurring. The consequence was that electricity had been recommended for every disease and every symptom imaginable. As to Dr. Rockwell's cases, he thought he would find that those not treated by electricity would also terminate in the same favorable way.

DR. L. PUTZELL accepted the last remark of Dr. Jacoby as explaining much of the obscurity surrounding this subject. The physician was likely, in attributing good results to electricity, to overlook the natural history of the disease, which was toward recovery. He thought considerable could be done in the way of relieving symptoms, but that electricity would not cure an organic disease. In some cases the galvanic, in others the faradic, current would prove useful. For instance, the faradic current applied with a brush to painful points in neuralgia would often produce rapid and remarkable results. He believed Dr. Gray had said the trouble was that electricity was given empirically. Dr. Putzell thought that was the only way in which it could be given. He cited a case in which he accidentally found faradic electricity proving of benefit to varicose veins of the leg which had been intractable for twenty years. He then began applying it systematically, and within six months the varicosity practically disappeared.

DR. GIRDNER made some remarks on

THE ELECTRICAL STATE OF THE HUMAN BODY IN HEALTH AND DISEASE.

With one electrode in the mouth and the other in the rectum, variations in the electrical state were observed, the greatest variations taking place with fever. He thought the time would come when it would be considered as necessary to test the electrical condition as to take the temperature in disease.

DR. FREDERICK PETERSON said he had for several months been using a mixture of cocaine and aconitia in superficial neuralgias, causing the drug to enter the skin by the aid of electricity. By this means pain could be relieved in from five to eleven hours, but the method was not curative.

DR. WILLIAM H. THOMPSON remarked on the importance of distinguishing between the forms of electricity in therapeutic use. For instance, galvanism was a powerful chemical agent, while faradism had no chemical effect. He must agree with Dr. Starr that the action of the constant current was so uncertain that he could say little about it. On the other hand, the faradic current had one very definite effect, namely, that of stimulating the circulation in all the parts between the electrodes, and this was of special use in the restoration of muscles, whether the wasting were due to inflammation of their sheaths or to the withdrawal of nerve-influence. In lead palsy it was particularly of value in restoring the small muscles of the hand. The faradic current was also of value in the removal of exudations attending subacute inflammations, as in rheumatism of the joints, pleuritic effusions, congestive conditions of the liver and spleen.

DR. A. H. SMITH had obtained marked and immediate benefit from static electricity, as he could do from no other form, in soreness and stiffness of the wrist and other joints, due to exposure to cold.

Regarding Dr. Girdner's remarks, he thought the electrical variations observed were due to the accidental presence of some substance within the body. The same thing would be observed if the electrodes were brought in contact with a sponge which happened to have, for instance, a bullet within its meshes.

DR. STARR closed the discussion, and said he thought it had been rather unfavorable toward the many claims of electricity in therapeutics, and was against the view commonly expressed in text-books. Gowers deserved credit for being the first to show courage enough to say that electricity had not come up to the claims made for it. In physics there was a marked difference between the two poles, yet Dr. Gray had admitted that in therapeutics there was no known difference. The inference was that there was not much effect from electricity in therapeutics anyhow. With regard to his treatment of hemiplegia not followed by contracture by electricity, such cases got well anyway; if there were contracture, it would remain. That a weakened muscle might regain strength under electricity was undoubtedly true, for electricity exercised muscles. Dr. Rockwell had said that faradism acted on the intramuscular nerves, and these being paralyzed in peripheral lesions, faradism failed to produce contraction of the muscle, while galvanism, acting on the muscular fibres, did produce contraction. Dr. Starr claimed that such a statement of physics was absolutely erroneous. The reason why the faradic current did not produce reaction in the paralyzed muscle was that the interruptions were too rapid for the diseased muscle to respond. Make the connections slowly and contraction would follow. There was no difference between faradism and galvanism in this respect. There was only a difference in the method of applying the electricity, there being in the one case interruptions of the current, in the other, none. He took exception to Dr. Fisher's statement that a nerve was a good conductor of electricity. It had been proven to be a poor conductor. It was further true that the sympathetic system did not respond readily. He thought it was true faradism aided in causing absorption of exudates, but it was by stimulating the circulation, and this could be done as well by galvanism. He thought Dr. Smith's explanation of the phenomena observed by Dr. Girdner was correct.

NITRATE OF SILVER STAINING OF THE CONJUNCTIVA.—Dr. Grossmann had an opportunity of examining an eye which had been deeply stained with nitrate of silver. He found that the seat of the staining was not, as generally supposed, in the epithelium, but in the elastic fibres, the epithelium being almost free. The pigment grains were found to lie in a granular detritus formed by the breaking up of old elastic fibres.—*Medical Recorder.*

Correspondence.

ON THE USES OF ELECTRICITY IN MEDICINE.

To the Editor of The Medical Record.

Sir: In a communication which appeared in your columns to-day, Dr. R. W. Amidon makes the following statement regarding the recent discussion at the Academy of Medicine upon the uses of electricity: "Dr. Starr credited Gowers with being the first to express in print, in his very recent book on nervous diseases, ultra-conservative views on electro-therapeutics. As a firm believer in American common-sense, I protest against any such statement. That some of us eagerly swallowed the Continental bait ten or twelve years ago, I must admit, but that it has taken us twelve years to find out we were sold, I deny. Some of us at once set ourselves to personally and experimentally prove the correctness of the stupendous claims made by Continental electro-therapeutists, with the prompt result of finding most of them a lot of bubbles."

After citing his own views published in 1884, in a small volume of ninety pages, entitled "Student's Manual of Electricity," and said to have been delivered in lectures for three years prior to that time, he adds, "though not advanced by a European, it would seem as if these ideas were conservative enough, particularly as they were taught and published at a time when everybody else [!] was curing (?) with electricity locomotor ataxia," etc.

If I have done Dr. Amidon an injustice in omitting to refer to his little brochure, I regret my omission. But admirable in respect of clear and concise statement as that little book is, it does not appear to me to hold the prominent place in the estimation of the medical public which it perhaps deserves. I confess that it had escaped my recollection when preparing my paper. In it the statement is made that "under treatment will be discussed *only* therapeutic applications of electricity which the writer himself has found of undoubted utility in his practice." The work, then, is founded upon a limited experience. It appeared too soon after the larger works of Erb (1882), Dujardin-Beaumetz (1883), Althaus (1883), and others to contain any really critical experimental tests of their assertions, and therefore it had only the value of a controversial statement. And while I am glad to admit that Dr. Amidon's position has been to some extent borne out by the experience of others, yet I think that his statements carry more weight to-day than they did at a time when they were almost prophetic in character. A criticism of any method of treatment can only be fairly made after very long and very patient trial; and a criticism of such measures as are employed in electro-therapeutics must be reserved for years, since it is claimed that it requires years of such treatment to obtain results.

The conclusion reached at the Academy, by the majority of the gentlemen who took part in the discussion, that the field of electro-therapeutics is a narrow one, carries much more weight to-day than it did when reached by Dr. Amidon alone in 1881 or 1884. Yet I regret that I did not mention his opinion in the discussion.

While I do not think that I can be justly accused of an undue bias of opinion in favor of European as opposed to American work, I regret that in the advocacy of "American common-sense" Dr. Amidon should have selected electro-therapeutics; for it is, unfortunately, to American authorities that much that is erroneous in the claims of electro-therapeutics is to be traced. It seems to me that scientific observation should not be hampered by national prejudices, even those which are apparently patriotic.

Yours, very respectfully,

M. Allen Starr.

22 West Forty-eighth Street, New York,
March 30, 1889.

A Christian Science Teacher defines cancer as "an accumulation of discordant thought."

New Instruments.

AN IMPROVED NASAL INHALER.

By BEVERLEY ROBINSON, M.D.,
NEW YORK.

The object of the little instrument shown in the accompanying illustration is to facilitate the use of dry vapors in the nasal passages. Thus far I have never seen any cheap and practical apparatus for this purpose, the nearest approach to such a one being the inhaler figured in my work on "Nasal Catarrh." The great objection to that instrument is that it is not self-retaining, and also that it is too bulky and does not answer the purpose intended, since it does not vaporize volatile drugs sufficiently. The instrument here shown is simply a hollow cylinder of hard rubber, an inch and a half long, and three-quarters of an inch in diameter, surmounted by a nozzle with convex outline, by means of which it is made self-retaining in the nares. Near its inferior margin are a number of small perforations, and within the cylinder is a bit of fine sponge retained in position by a transverse pin. Any volatile liquid substance, such as creasote, eucalyptol, pine-needle oil, etc., may be used with this inhaler. Another advantage which the instrument possesses is its small size (the cut represents the actual size of the inhaler), by reason of which it can be carried in the pocket, and used at any time during the day as may be required.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 24 to March 30, 1889.

An Army Medical Board will be in session in New York City, from May 1 to 31, 1889, for the examination of candidates for appointment in the Medical Corps of the United States Army, to fill existing vacancies. Persons desiring to present themselves for examination by the board will make application for the necessary invitation to the Secretary of War, before May 1, 1889, stating the place of birth, place and State of permanent residence, and enclosing certificates based on personal knowledge from at least two persons of repute, as to American citizenship, character, and moral habits. Testimonials as to professional standing, from professors of the medical college from which the applicant graduated, and of service in hospital from the authorities thereof, are also desirable. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a regular medical college, evidence of which, his diploma, must be submitted to the board. Further information regarding the examinations and their nature may be obtained by addressing the Surgeon-General, U. S. Army, Washington, D. C.—John Moore, Surgeon-General, U. S. Army, Surgeon-General's Office, Washington, D. C., April 1, 1889.

Barnett, Richards, Assistant Surgeon. Died March 27, 1889, at Fort Riley, Kan.

ALEXANDER, R. H., Lieutenant-Colonel and Surgeon. C. O., at Los Angeles, Cal., reports his death on March 29, 1889, at 11:50 A.M.

MAUS, LOUIS M., Captain and Assistant Surgeon, Fort Schuyler, N. Y. H., will proceed to Camp S. B. Luce, Fisher's Island, N. Y., with battery "K," 5th U. S. Art., and report to the Camp Commander for a tour of rifle practice. Par. 10, S. O. 158, Headquarters Division of the Atlantic, Governor's Island, New York City, March 21, 1889.

Atlanta Barracks, Ga. Established by G. O. 28, A. G. O., March 21, 1889.

Official List of Changes in the Medical Corps of the United States Navy for the week ending March 30, 1889.

BERRYHILL, THOMAS A., Assistant Surgeon. Detached from Naval Academy, Annapolis, Md., and to the Naval Hospital, New York.

HEFFENGER, A. C., Passed Assistant Surgeon. Ordered to appear before the Retiring Board, Washington, D. C.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 30, 1889:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	5	4
Scarlet fever	480	58
Cerebro-spinal meningitis	4	2
Measles	158	13
Diphtheria	172	47
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

COLDS AND CLOTHING.—The teaching of modern science and of ancient custom goes to show that heat production within the body has much to do with the tissue changes concerned in muscular activity and with healthy digestion. It is conserved by warm and moderate, wasted in evaporation by excessive, clothing. Finally, by a simple nervous reaction, it is increased after the contact of external cold. It follows from these observations that if we be so clad with comfortable underclothing that surface perspiration is not formed in excess and is rapidly removed; one great cause of chill—sudden evaporation—is done away with. Outer cold, then, provided it is not too severe, only touches, as it were, the spring of the heat-making metabolism, and, exciting an elastic rebound in the chain of vaso-motor fibres, awakens that oxidative action by which every tissue is made to yield its share of heat to the body. This bracing influence is lost wholly or partly to those who are too heavily clothed, and in its place we may have a dangerous excess of surface heat. It is for this reason that we have before protested, as we now do, against the indiscriminate use of the thick and heavy overcoat. We would rather see men in fairly robust condition, especially if young, clad warmly next the skin, and wearing either a light top-coat or none at all. There can be no doubt that the habitual use of great-coats is indirectly accountable for the chills which they are intended to prevent. Were the overcoat worn continuously it might attain its object. Its intermittent use, even when ample underclothing is worn, affords no solid guarantee of safety, but rather the reverse. The man of sedentary habits has especial need to remember this. He emerges daily from a warm breakfast-room clothed in his ordinary winter garments, with probably woollen underwear, and over all the heavy ulster or top-coat. After a short walk he finds that the sense of warmth he began with is more than maintained. He arrives at his office or place of business, and off goes the overcoat though the air of the newly opened room is as cold as that without, and draughty in addition. During the day perhaps he travels to and from adjacent business houses wearing only his house clothing. The overcoat is laid aside till closing time reminds him of the journey home. The frequent result is that somehow between the hours of his departure and return he is chilled. No doubt he would run as great a risk if, lightly clad, he were to face the rigor of a winter day. In this case, however, exercise and habit might do much to develop the power of endurance, and there would, at all events, be less danger of sudden cold acting upon a freely perspiring surface. Woollen underclothing represents a state of healthy comfort intermediate between these extremes, and more resistant to chill than either. In commending its use, however, we do not assert that the influence of age and constitution is to be overlooked. Youth can oppose a power of resistance to depressing agencies which does not reside in the worn-out nerve-centres of a riper age. Similarly, that elastic reaction which characterizes the nervous and sanguine types is not to be looked for in the lax tissues of the lymphatic. The weaker physique naturally calls for fuller protection than the stronger; and any rule requiring the disuse of the overcoat should allow of reasonable exceptions in favor of the old and constitutionally feeble. Unusual severity of weather, especially if associated with night-air and the loss of sleep which this implies, is another condition which might well constitute an exception. In such a case we are compelled to add some form of overcoat to the ordinary amount of clothing. Some parts of the body—for example, the chest, throat, and feet—are certainly more susceptible to cold than others. As a useful safeguard, cold or tepid bathing of such parts is in merited favor. The custom so common with many persons, especially women, of walking out in thin-soled boots often plays an important part in catching cold. The progress of time and of rational thought may be expected to bring in a more comfortable arrangement by clothing the foot in woollen hosiery and a stouter boot.—*The Lancet.*

THE PARALDEHYDE HABIT.—A case of this kind is described as occurring in the person of a maiden lady of forty-two years of age who, through the assistance of her physician, was conducted from the use of morphine and chloral into that of paraldehyde, and he could get her no further. All attempts at abandoning the pernicious habit have been futile. The lady now consumes one ounce or more of the drug daily, and has taken as much as twenty ounces in twelve days. She cannot sleep unless under its influence, and when deprived of its use for a few hours she is languid, restless, miserable, suffering physical pain and mental depression, and she has no appetite. Unlike morphine deprivation she has no exhausting diarrhœa, muscular tremors, or "electric pains," when without the paraldehyde, but, like all remedies which exercise marked psycho-neural restraint after long-continued use, the patient misses, in a marked and painful manner, the sudden withdrawal of the long-accustomed nerve-impression. She has somewhat prematurely reached her menopause, and some of her irritability and debility may be due to that; but she is irritable, exhausted, and collapsed when the drug is not freely circulating in her blood.—*The Alienist and Neurologist.*

ACCIDENTS DUE TO INTRA-UTERINE INJECTIONS.—These are divided by Dr. Mangin, *Nouvelles Arch. d'Obs. et de Gyn.*, into accidents of three orders: 1. Accidents of retention. 2. Septic accidents. 3. Nervous accidents. He explains the first order by the slow absorption of the fluid injected and retained in the uterine and vaginal cavity; by the penetration of the liquid into the peritoneum by way of the Fallopian tubes; by the penetra-

tion into the circulation by the venous sinuses of the liquid injected. This variety he considers the most frequent and the most serious. Septic accidents, shiverings followed by fever, appearing always after a uterine irrigation and ceasing only after the injections are discontinued, are manifestly in correlation with these injections. The nervous accidents, which are always incriminated as soon as a complication after an injection arises, should be looked upon as exceptional. After fully describing the mechanism of the three orders of accident the author states that the nervous accidents are without gravity. This is far from true of the toxic and febrile accidents, which ought and can be avoided by certain precautions, as the securing of a catheter by which the return of the liquid is made certain, and to be careful not to raise the vessel containing the liquid more than thirty centimetres above the bed.—*The American Lancet.*

THE SURGICAL TREATMENT OF PURULENT PERICARDITIS.—The successful case related by Dr. Dickinson at a meeting of the London Clinical Society will again direct attention to the treatment of purulent pericarditis by free incision and drainage. Dr. Dickinson's is now the third published case treated by incision and drainage that has recovered. Notes of the two former cases were given in a paper read before the Royal Medical and Chirurgical Society, in 1883, by Dr. S. West, and published in vol. xlvi. of that Society's "Transactions." The first case was one of Professor Rosenstein, the patient being a boy aged ten; the second case was that of a boy aged sixteen, treated by Dr. S. West; and now this third case (Dr. Dickinson's) was also a boy, whose age was ten. Many fatal cases have besides been recorded, so that the operation may not be lightly undertaken. Purulent pericarditis however, is usually so fatal a disease that severe measures may be justifiably employed for its treatment; and, although the physical signs which accompany it do not always enable the physician to diagnose with certainty between it and serous pericarditis, it is always possible to undertake a puncture for diagnostic purposes. With regard to this especial point of the diagnosis, it is to be noted that in purulent pericarditis a friction-sound is usually absent; but, the diagnosis having been settled by the exploratory puncture, and treatment by incision and drainage determined upon, the place of puncture must be settled. It is usually recommended to make the incision in the fourth or fifth intercostal space; but in Dr. Dickinson's case the fifth right space was chosen by Mr. Rouse, the operator. Mr. Godlee, at the meeting, exhibited some drawings showing the relation of the internal mammary arteries to the edge of the sternum in children, from which it appeared that if the operation is done very close to the sternum the vessel of the side selected is very apt to be wounded; and he recommended that the vessel should be cut down upon and tied before the pericardium is opened. Dieulafoy recommends the fifth left space, about one inch from the edge of the sternum, as the best site for puncture with the aspirator. The purulent pericardial sac being opened, and the fluid drawn off, the relief to the patient is usually at once extreme; the pus should then be allowed to drain away through a tube until recovery ensues. The drainage was facilitated in Dr. Dickinson's case by the patient being placed face downward in bed. The elasticity of the pericardium further tends to empty its cavity. Altogether, it is allowable to hope that a fair chance of success will attend this operation in the future when it is undertaken with full antiseptic precautions.—*The British Medical Journal.*

CASE OF ASCITES SIMULATING OVARIAN TUMOR.—At the Medical Society of London (*The British Medical Journal*, November 17, 1888), Dr. Gulliver read the notes of a case of ascites simulating ovarian tumor, in a patient aged sixty-three. She was admitted on August 24th, and died on October 4th. Her symptoms previous to admission were pain in the back and inability to retain her urine. There was, however, nothing to indicate renal disease. One month before admission the legs and abdomen began to swell, and she was subject to attacks of vomiting. When admitted she was very emaciated. The thorax was normal, but the abdomen was prominent. The whole front of the abdomen was dull on percussion, the dulness being more marked on the right side, which was bulged. The dulness extended from the ensiform cartilage to the pubes. There was a zone of resonance over the left flank. At this time the diagnosis was in favor of an ovarian tumor. On the right side the thrill of fluid was obtainable. On September 8th, ten days after admission, she was tapped, and seven or eight pints of fluid was drawn off; the fluid resembled ascitic fluid, presenting none of the characteristics of ovarian fluid. Immediately after the withdrawal of the fluid the dulness became more unilateral, disappearing from above and to the left side. The dulness, however, remained over the lower two-thirds of the abdomen on the right side, and later on resumed its original extent. There was vomiting, but no signs of obstruction of the bowels. Albumin was now found in the urine, and this, together with the age of the patient, precluded the idea of operative interference. The diagnosis at that time lay between ovarian tumor and ascites shut off by vertical adhesions. She died on October 4th. On opening the abdomen a considerable quantity of ordinary ascitic fluid escaped. The whole interior of the abdomen was lined by a smooth, thickened membrane, extending from the under-surface of the diaphragm down to the pubes. On the right side it formed a continuous sheet across the front of the abdomen, with a free border on the left side; it covered in most of the abdominal viscera. On the left side were coils of small intestine fixed down by adhesions. The organs themselves were apparently healthy. Many of the appearances simulated horizontal localized ascites.

A WARNING AGAINST THE USE OF COCAINE IN HAY-FEVER.—Dr. Windle records in the *Birmingham Medical Review* his personal experiences with cocaine in the effort to obtain relief from hay-fever. He says: "During the first fortnight or three weeks of the administration of cocaine, I can scarcely describe the delightful effects which it produces. It removes within a minute or two after its absorption all sensation of fatigue, bodily and mental, and produces a most pleasurable capacity for work apparently. I say apparently, because I doubt if it would be possible to do anything which required great concentration of mind while under its influence. As a matter of fact, I have found it very hard to do original work under these conditions. During this time, too, there is very little reaction after the use of the drug. But after a short time conditions change, the drug begins to act less powerfully, requiring a stronger solution and more frequent application, and coupled with this there is experienced a great reaction. It is difficult again to give an idea of the amount of this. I can only say that during the period alluded to, especially if one has necessarily a good deal of work to do, the prostration, I can use no other word, which follows upon the use of the drug is most severe. This, however, is not all, for the appetite is decreased and sleeplessness induced. The action of the heart becomes rapid and unsatisfactory, and the whole nervous system is brought into a highly strung, overwrought condition. I can assure those who hear me that I have not overdrawn this side of the picture. So strongly is it impressed upon me that, in spite of the great annoyance and even suffering produced by hay-fever, and the relief afforded by cocaine, I am very doubtful whether I shall venture to run the risk of using it during another season."

In conclusion, he says that the lesson which he has learnt is that while cocaine as a remedy affords a palliation, perfect for all practical purposes, it is a drug whose use is accompanied by so many collateral disadvantages as to make it very doubtful as to whether its continued exhibition, during five or six weeks, is a line of treatment which it is safe or justifiable to enter upon.

Original Lectures.

ON PHAGOCYTES.[1]

By WILLIAM OSLER, M.D.,

PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.

THERE are in the body groups of tissues possessing cells which either normally display amœboid changes or are capable, under certain conditions, of assuming them. By amœboid properties we mean not only the capability of free movement, but the possession of a power which enables a cell to take foreign particles into its interior. Tissues containing such cells are derived from the mesoderm, the type of which, phylogenetically, is a free wandering cell (Minot). In the development of this layer epithelial and non-epithelial portions may be distinguished. For the former Minot has suggested the term mesothelium, and the latter His calls mesenchym. The distinction between the two is, however, largely artificial, as the epithelium may be, and in places is, in development changed into connective tissue. And, thirdly, there are in the mesoderm, at all stages of its development, certain cells which are free and independent—mesamœboids (Minot)—and which persist subsequently as leucocytes.

These mesodermic cells in the adult body, which are capable either of free amœboid movements or of taking into their protoplasm solid particles of various sorts, are met with:

(1) As the colorless corpuscles of blood and mucus.

(2) The connective-tissue cells, free and fixed, within the connective tissue proper, or forming the supporting framework of the solid organs.

(3) Cells of the spleen, bone, marrow, and lymph-glands.

(4) The vascular and lymphatic endothelium.

(5) The alveolar epithelium of the lungs.

All of these cells possess, in a greater or less degree, the power of taking solid particles into their interior—virtually, as we say, of eating them.

On account of the possession of this property, Metschnikoff has suggested for these groups of cells the term *phagocytes*, as expressive of their most distinctive feature, and for the process in general the term phagocytosis.

He regards this function as a property handed down from the primitive unicellular organism, and traces in an interesting manner the evolution of cells possessing it throughout the animal kingdom; attempting to show a genetic relation, physiologically at least, between the free living rhizopods and the cells of the middle germinal layer of the higher animals. Not a little of the attractiveness of Metschnikoff's views is derived from the glamour of evolution thrown over them, by thus attributing the retention in certain cells of an atavic property in the highest degree useful to the organism.

I shall consider first the action of these phagocytes as normal physiological factors in the work of the body; and, secondly, take up the theory that these bodies play an essential *rôle* in the protection of the organism from the invasion of specific germs.

And, first, two illustrations from comparative physiology to indicate the important part assigned to phagocytes in certain transformations which animals undergo. In the development of the frog, the removal of the tail of the tadpole, and of the gills, by gradual atrophy, is effected, according to Metschnikoff, by the activity of the amœboid cells. At a time when the hind-legs begin to bud, the leucocytes migrate into the tail, and by their phagocytic action remove the tissue, fragments of which, as muscle, bits of nerve-fibres, etc., may be seen in the interior of their protoplasm. The gills are absorbed by an identical process. In the transformation of the larva into the fly, Kowalewsky[1] has shown that the large masses of muscle-tissues, so abundant in the larva, and other parts unnecessary in the matured condition, are removed by the activity of the phagocytes.

It has long been known that foreign bodies, such as ligatures, portions of dead bone, and other substances, may be completely removed by leucocytes. Interesting as is this, and bearing directly upon the question, I propose to limit myself entirely to the consideration of the two aspects above referred to.

Nowhere in the body do we have such a facility for studying the action of phagocytes as in the organs of respiration, in which, with the cilia of the bronchial mucosa, they share in the work of cleansing the air-passages; and of these two important agencies it is hard to say which plays the more important part in the expulsion of those particles of foreign matter which, in cities at least, we constantly inhale. There are several groups of cells engaged in this work: The ordinary mucous corpuscles; the alveolar epithelium; the connective-tissue elements of the pulmonary stroma, and the leucocytes of the lymph-tissue in the bronchial, tracheal, and mediastinal glands.

The mucous corpuscles, which in health are derived largely from the muciparous glands, and in inflammatory states from the general bronchial mucosa, are actively concerned in attacking the dust which reaches, in ordinary inspiration, as far at least as the medium-sized tubes.

The examination of the morning sputa of a cigarette-smoker, or of a person who has been exposed to a dusty atmosphere, shows very clearly that no small proportion of the carbon grains is included within protoplasm. The free granules are abundant, but almost every leucocyte has its little load which it has picked up on its road from the finer tubes to the trachea. I have always thought this represented a neat bit of economy of labor, as there can be no question that it is easier for the cilia to sweep half a dozen angular particles, when enclosed in a cell, than to work at the same when free. In all probability, the finer particles which fall upon the tracheal or the bronchial membranes are gotten rid of almost entirely by cells and cilia. There does not appear to be, to any great extent, penetration of pigment-granules between the ciliated epithelium. It is unusual to see beneath the tracheal mucosa any collection of carbon grains. We do meet with it in the submucous bronchial tissue, but the active vibratile lining seems to afford a tolerably sure protection. The lymph-vessels open on the surface in the pseudo-stomata, and in the experimental work of Arnold[2] and others, leucocytes carrying black grains have been seen in the submucous lymph-vessels; yet the process does not seem to go on to any great degree.

The particles which reach the air-cells find no active current to sweep them from the spots on which they fall.

[1] An Address delivered before the Alumni Association of Bellevue Hospital, New York, April 3, 1889.

[1] Zeitschrift für wissenschaftiche Zoölogie, Bd. xlv.

[2] Untersuchungen über Staubinhalation und Staubmetastase. Leipzig, 1885.

It is possible to conceive, under certain conditions, of the air-cells gradually filling, were it not for the activity of phagocytes, derived largely from the alveolar epithelium, which stands, as it were, at the gateway of the lymphatic circulation.

The cells lining the air-cells, seen, for instance, by scraping gently the cut surface of an œdematous lung, look as flattened, desiccated, and lifeless as do the scales of the scarf-skin. But appearances are deceptive in this case, and the protoplasm of these cells is not only active, but probably varies much in shape with the distention or contraction of the alveoli. When in contact with liquids and in pathological conditions, they change so much in form that I find it often a difficult lesson to teach students familiar with normal histology only to recognize, in the large, swollen ovoid cells so common in sputa, alveolar epithelium. Moreover, from the rapid way in which they may be desquamated, there must be ample provision for their rapid restitution. How far, in a normal state, these cells take part in the work of cleansing the lungs is not yet definitely settled. In the young they do not often appear in the sputa, except when there are indications of catarrhal changes, but in the adult their presence is very common. It is rare to see one in the sputa of a hospital patient which has not brought with it a load of carbon, all of which may not have been derived from the air-cells, as these bodies can undergo amœboid changes, and, like the leucocytes, are probably not above picking up a grain or two in their course toward the larynx. In cases of bronchial catarrh, and in phthisis, these pigmented cells of the alveoli may be very abundant, producing the blackish streaks which may be seen with the naked eye. When these cells have undergone the myelin degeneration they seem no longer capable of performing scavenger work.

In coal miners, or even in stokers and coal heavers, these pigment-laden cells may be extraordinarily abundant. It is not only when the patient comes direct from the mines, or from the coal yards, but the old *poitrinaires* who haunt in such numbers our city hospitals, expectorate for months, or even longer, sputa containing the pigment-laden alveolar cells, staining the entire expectoration. So persistent may this be that the process may be regarded, not simply as an extrusion of the daily dole of carbon, but as a definite excretion, if we may so use the term, of particles which have been stored up in pulmonary parenchyma.

A certain proportion of the inhaled dust-particles escapes the mucus-cells and the alveolar epithelium, and penetrates the substance of the lung, entering at the *kittsubstans* between the cells, or through the pseudo-stomata existing in the alveolar wall. The particles of coal dust have such sharp angles that we may suppose them capable of mechanically lacerating the delicate alveolar cells.

In dwellers in the country, as well as in wild animals, breathing an air comparatively pure, the cilia and the phagocytes in the air-passages appear quite able to prevent access of the carbon grains to the lung-tissue; whereas in the dwellers in the cities, and in animals kept in confinement, the impurities in the air are so abundant that these agents are insufficient, and sooner or later the grains penetrate the air-cells, aided no doubt by the movements of inspiration and expiration; and we have the well-known marbled or carbonized organs which we see every day upon the post-mortem table.

When the particles reach the lymph-spaces, the fixed and free connective-tissue cells of the stroma join actively in the work. On section we see in the alveolar septa large numbers of round protoplasmic bodies, two or three times the size of colorless blood-corpuscles, which are usually packed full of dark grains. A certain proportion is seen within the ordinary connective-tissue corpuscles, and in addition there are, in variable numbers, ordinary leucocytes. But even these forces are insufficient to meet the constantly advancing stream of dust-particles. The destiny of those which escape the phagocytes in the alveolar stroma has been accurately followed in the investigations of Arnold and others.[1] Entering the lymph-stream they are carried first into the lymph-nodules which, in the lungs, surround the bronchi and blood-vessels, and a large number become fixed in the cells of the follicular cords or are permanently embedded in the stroma.

As they pass along the lymph-channels into the interlobular septa beneath the pleura, a still further number lodge and become permanently enclosed in the stroma-cells, and, finally, the remnant pass into the larger lymph-channels and ultimately lodge in the bronchial and tracheal glands. Here the lymph- and stroma-cells of the follicular cords dispose of them permanently. That this is effected in great part by the phagocytes is, I think, unquestioned. A scraping from any moderately pigmented lymph-gland shows that the chief part of its carbon load is warehoused (so to speak) in protoplasm; the granules lie for the most part embedded free in a connective-tissue matrix. Here the struggle is practically over, and though not a victory, yet the compromise which has been made is the best which could possibly be effected. The sharp irritating particles have been placed in a position in which they could do the least harm, and, though not expelled, have been safely imprisoned.

Once in the lymph-glands of the bronchi, it is thought they never reach the general circulation, but it has been shown of late years that under certain circumstances the carbon particles may pass the bronchial filters and spread far and wide throughout the system. Soyka's remarkable case, in which undoubted coal particles were found in the tissue of the spleen and of the liver, illustrates what really may occur. Weigert[2] in particular has called attention to the frequency with which, in the spleen and in the liver, carbonization of the connective tissue occurs. He states that it results whenever densely pigmented bronchial glands form close adhesion to the pulmonary veins, through the walls of which the carbon particles pass and so reach the general circulation. I would not call the condition common, but I have seen at least three instances at the Philadelphia Hospital in which the ir regularly distributed pigment in the spleen and in the liver (in the latter chiefly along the portal canals) was undoubtedly of extraneous, not of hæmic origin.

The steps in this process described may be followed in the lungs of any town-dweller, but to see in perfection the remarkable activity of the pulmonary phagocytes, one must study the early stages of anthracosis, particularly in those exceptional cases which we see occasionally when a miner has been killed by accident or dies of acute disease. It is not, I think, too much to say that the larger part of the pigment contained in lungs almost, if not quite, black, is enclosed in protoplasmic cells. Here too the invading particles are more formidable and not so readily dealt with; yet one frequently finds long irregular bits completely encircled by a film of protoplasm which the phagocyte has stretched to the utmost, just as we may see an amœba extend along the whole length of one of the short rod-like diatoms.

I know of nothing which illustrates better the remarkable amœboid properties of human protoplasm than a slide prepared from the scraping of such a lung, or of the black juice pressed therefrom. Scarcely a leucocyte can be seen which has not been at work, and many of the larger cells have the protoplasm stuffed to the full with carbon grains. Only in the work of the pond amœbæ, preying among desmids, diatoms, and algæ, can we see such better illustrations of active work. There is, of course, this difference, that the amœba eats to live, and so far as I know, never loads its protoplasm with useless stuff. The body phagocytes take anything, never exercising selective powers. The particles which gain entrance to the lungs may be far too large for a single phagocyte to attack successfully. I have sketches showing rod-like

[1] See recent work of Fleiner, Virchow's Archiv, Bd. cxii.
[2] Fortschritte der Medicin, Bd. i.

particles, the ends of which appear enclosed in protoplasm of a dumb-bell shape; while in one instance not only were the ends enclosed, but the central portion was completely enveloped by the third leucocyte.

A physiological process in which phagocytes play a leading *rôle* is the removal and disintegration of the red blood-corpuscles which have lived their life and are no longer fit for work. The cells containing the red blood-corpuscles which are found in the bone-marrow and in the spleen, however much opinion may differ as to their mode of origin, cannot, I think, be regarded in any other light than as phagocytic elements with this definite function. They exist normally in the red marrow and in the spleen, and we may recognize (1) cells which appear to be, from their size and shape, elements of the pulp, and (2) cells which belong to, or are derived from, the endothelium of the capillaries, and (3) the cells of the stroma. The gradual production of the pigment in this way has been so often described, and is so well known, that I need not now dwell upon it. In certain morbid conditions we see this process widely extended, and we find cells containing red blood-corpuscles in the liver, in the lymph-glands, even in the blood itself; and particularly is this the case in those states associated with rapid blood deterioration and destruction, as in acute fevers, when these bodies may be enormously increased. In certain forms of anæmia so abundant are they in the bone-marrow and in the spleen that they have been regarded as directly concerned in the wide-spread hæmopthisis.

The observations of Quincke[1] and his pupils have shown that the liver is the chief seat of blood-destruction in pernicious anæmia, but the totally different appearance presented by this organ, even in long-standing cases, to that met with in malaria, shows a radical difference in the nature, possibly in the seat of the hæmolytic action. In the former case the pigment is chiefly in the liver-cells; in the latter, in the stroma and about the blood-vessels. We cannot from this regard pernicious anæmia as an hepatic disorder. The liver, probably, makes the best disposal it can of an abnormally large amount of coloring matter, which is, I should suppose, not brought to it in the same form as in malaria, but rather in a form similar to the raw material of the bile-pigment, which would account for the active participation of the liver-cells. The deep beefy-red color of the muscles in pernicious anæmia also tells of an abnormally large quantity of coloring matter at the disposal of the tissues.

In chronic emphysema, in mitral obstruction, and in all affections in which the circulation within the lungs is permanently embarrassed, the condition of brown induration which ensues affords a very beautiful illustration of the same process. The blood-corpuscles by diapedesis reach the stroma of the air-cells, where they are seized upon, just as are coal particles, by the connective-tissue cells and are gradually converted into a pigment which retains for a long time its brownish tint, but which may ultimately become black.

Neumann, in a recent paper,[2] doubts whether the brown induration of the lungs is really the result of the ingestion of the red blood-corpuscles by the stroma-cells. He holds that in many instances, at least, structures within the corpuscles, which resemble so closely the red blood-disks, are in reality only pigment-forms having the size and color of the red blood-cells. We certainly see structures within the cells which cannot possibly be mistaken for anything but red blood-corpuscles, and I think the expert eye can usually discriminate between such and the round aggregations of pigment, however deceptive may be their form and color.

Phagocytosis has been studied in the process associated with absorption of extravasated blood. Langhans was the first to show that blood effused into the tissue did not simply disintegrate and disappear, but that the connective-tissue elements were actively at work, and that no small proportion of the colored corpuscles was ultimately taken into the interior of their protoplasm. This has been amply confirmed, and I think there can be no question as to the fact, but observers are by no means unanimous, however, whether the phagocytes are essential in the process. Probably in large extravasations only the peripheral parts are dealt with in this way. The fixed connective-tissue cells with migrated leucocytes all share, I believe, in the process. It must not be forgotten, as Neumann has pointed out, that pigment-granules in the interior of the cells may resemble blood-corpuscles very closely. However this may be, there can be no doubt that the cells are concerned in the transformation of the hæmoglobin; whether they take it up with the corpuscles or after it is diffused from them.

Remarkable differences exist in the final transformation of the hæmoglobin, resulting in the formation of two pigments—hæmatodin, which develops chiefly in the central parts of the extravasation, and an albuminate of iron, hæmosiderin (Neumann), which is formed at the boundaries of the clot and wherever the coloring matter comes in contact with the tissues. That this difference is related in some way to the influence of the cells is in the highest degree probable, though Neumann is not inclined, from his observations, to attribute an important action in this respect to either the fixed or wandering connective-tissue elements. The question is one to which a few years ago I gave some study in connection with development of cells containing red blood-corpuscles, and I was much impressed with the truth of Langhans' statement as to the frequency and numbers of these structures in the vicinity of extravasations of all kinds.

In the intestinal canal the leucocytes assist, to some extent at least, in the absorption of fat. Schaefer's observations upon this point[1] show very clearly that during digestion the amœboid cells of the mucous coat become filled with fat-globules. How these are obtained we do not as yet know clearly. Whether the fat penetrates between the epithelial cells, or whether the leucocytes pass up between the cells reaching to the surface and here securing the fat, has not been definitely determined; though from the presence of an occasional cell, or even a nest of cells between the cylinders, the latter view is probably the correct one. The leucocytes pass to the central lymph-vessels, where they disintegrate, and discharge their load of fat-granules, which has, meanwhile, in the protoplasm of the cell, been broken up into finer particles, which form the so-called molecular base of the chyle. Possibly, too, the leucocytes may take up other ingredients. It is interesting to note that in many of the lower animals the amœboid cells of the endoderm possess an active digestive function. The observations of Parker and Lankester appear to confirm fully the researches of Metschnikoff on the phenomena of intercellular digestion in invertebrates.

So far, we have been dealing exclusively with the action of phagocytes under normal conditions. And it is clear that these mesodermic cells have important functions throughout the life-history of the organism. Not only in the early steps in the development of the blastoderm do we see them actively at work, but in various stages of development, particularly in that of the bone, their action is of the first importance. In the mature body we have seen that in the lungs, in the intestines, and in the blood-making organs, the phagocytes have most essential functions, but the question of chief interest to-day relates not so much to this normal process, about which there has been so much doubt, as to the supposed part which these cells take in protecting the body against the invasion of parasites.

The theory elaborated by Metschnikoff had been hinted at by many previous observers, but to him is undoubtedly due the credit of bringing it into prominence,

[2] Virchow's Archiv, Bd. cx.

[1] Monthly International Journal of Anatomy and Physiology, 1885

and of doing in connection with it a very large amount of interesting work. It must be allowed that he came to his task well prepared. Many of us can look back with pleasure to his brilliant investigations upon the intercellular digestion in the planariæ and in sponges, carried on largely at the Naples Marine Station; investigations the truth of which, so far as I know, has not been controverted. Following these studies, directly in the same line, was his interesting research into the method of the absorption of the tail of the tadpole, already referred to, in which he appears to have demonstrated that the atrophy of this organ results in reality from the active removal of the fragments of the tissue by leucocytes.

So far the work was biological, and had no direct bearing upon the phenomena of disease further than that, in the latter illustration, it bore out the well-known fact of the absorption by leucocytes of foreign bodies placed within the tissues. In 1884, vol. xcvi. of Virchow's *Archiv*, he published a paper [1] which arrested the immediate attention of students in parasitology. It is now too old a story to narrate at length; it will be sufficient to remark that in the daphnia, the common water-flea of the aquarium, he had studied the relation of the leucocytes to a fungus with which these insects are prone to be infected. The phagocytes attack the fungi which enter the body-cavity from the intestines, and practically eat them, enclosing them in protoplasm. Where one cell is insufficient, several combine to enclose the spores in large plasmodia-like aggregations—giant-cells. If the invasion was in such large numbers, and the activity of the fungus so great, that conidia were formed, the resisting forces were insufficient; victory remained with the enemy, which meant the death of the daphnia. Of 100 insects studied, 73 became infected, of which 59 recovered and 14 died.

Following this line, Metschnikoff proceeded to study the relation of leucocytes to anthrax bacilli, to the micro-organisms of erysipelas, and to those various other affections. He likened specific inflammation to a warfare in which the invading army is represented by micro-organisms, and the resisting forces by the leucocytes. Even in details the analogy was maintained. Notice of the arrival of the invaders was telegraphed, so to speak, by the vaso-motor nerves; the line of communication, the avenues of mobilization, were represented by the blood-vessels. The aim of the invader is to secure the territory, to rapidly multiply, to live at the expense of his host, and to manufacture and circulate substances injurious to him. The aim of the resisting forces is to encircle the enemy, enclose him, digest him, and render him inert in battle. Many phagocytes die in the process, and, if in large numbers, the heaps of the slain represent pus; an abscess is a battle-ground densely packed with dead bodies. If victory remains with the invaders the organisms pervade the affected part, multiply, and induce conditions incompatible with the life of the part, or perhaps with the life of the entire organism. If the battle is with the host, the parasites are destroyed, perhaps not without loss, but the normal state is gradually restored. Practically, on this theory each organism is regarded as possessing a standing army composed of mesoblastic cells, capable of rapid reproduction and rapid concentration, one important function of which is to protect the organism against destructive agencies invading it from without. Certainly a most attractive theory, fully deserving the attention which it has aroused. On the one hand widely accepted, on the other bitterly assailed, the question is as yet far from settled, and to the position in which it stands I propose briefly to refer, and then to offer some results of my own observations upon a disease in which special facilities exist for the study of the problem.

Metschnikoff has studied a number of diseases, erysipelas, anthrax, relapsing fever, and tuberculosis, with a view to finding facts in support of this theory, and his communications within the past four years have been numerous and elaborate.[1] They have been so widely abstracted and so often referred to that I shall not occupy your time by entering into details, but will briefly indicate the chief points upon which he lays special stress in these different affections, and note certain of the observations which have been made by other workers.

In erysipelas the cocci are attacked first by the leucocytes filling the lymph-spaces, which rapidly proliferate, and actively eat the micro-organisms. Not alone do the colorless corpuscles act as phagocytes, but the fixed connective-tissue cells assist in an important manner. In cases of recovery he found that behind the advancing cocci the leucocytes were crowded with parasites which showed evidences of digestion and destruction. The connective-tissue cells do not appear to attack the cocci, but are chiefly concerned with the absorption of the inflammatory exudate, even taking up the leucocytes which have died. In fatal cases there was enormous development of micrococci, the majority of which lay free in the tissues not enclosed in the phagocytes. Inoculations with erysipelas cocci in white rats confirm these observations made in man. The leucocytes attack the parasites, which undergo rapid degeneration in the protoplasm. The larger connective-tissue cells, macrophages, did not attack the cocci. Metschnikoff recommends experiments upon these animals with the erysipelas cocci as an especially favorable field in which to study the struggle between the cells and bacteria.

In anthrax Metschnikoff has studied the relation of the phagocytes to bacilli introduced into frogs, which, as is well known, possess immunity at the ordinary temperature, but succumb when the temperature is raised. A graft of a piece of anthrax tissue under the skin of a frog is, within from fifteen to twenty hours, surrounded by leucocytes, which take up many bacilli. According to Koch, they may grow inside the cells and even burst them, but Metschnikoff holds that the anthrax filaments do not develop within the cell, but are gradually destroyed by them, and that this is the reason why the frog at an ordinary temperature recovers. In the heated frog the bacilli rapidly develop, and, the efforts of the leucocytes proving insufficient, the animal dies; not, it is asserted, from any inactivity on the part of the leucocytes, but because the bacilli secrete a liquid which protects them from attack.

In Baumgarten's criticism [2] he relates some experiments with the anthrax bacilli which directly antagonize these observations. Pigeons do not die when inoculated with anthrax, and he found that the bacilli injected degenerate in precisely the same way in these creatures as when in distilled water; only here and there did the leucocytes contain the rods.

He found that in frogs, though the bacilli are eaten by the leucocytes inversely to a degree of heat to which the animal is exposed, there is never total destruction of the bacilli by the phagocytes.

Hess [3] has performed experiments which bear directly upon these points. Anthrax cultures in Zeigler's glass chamber, inserted beneath the skin in animals not very susceptible to the disease, as dogs and birds, showed active migration of the leucocytes into the chamber, which appear to attack the bacilli and to destroy them. These very striking experiments certainly indicate what, of course, is well known, a high degree of activity on the part of the leucocytes, finding their way, as they do, into the chamber closed at all points except one narrow orifice. But, as Hess says, it is a question whether the disintegration in the cells necessarily means destruction by the cells.

In relapsing fever, Metschnikoff states that the spirilli are not attacked by the leucocytes in the blood, but are destroyed only in the spleen. In the artificially produced disease in monkeys, he finds abundant inclusion of the spirilli in the phagocytes of the spleen during the period of the rise in temperature before the crisis. This, how-

[1] Ueber eine Sposspilzkrankheit der Daphnien.

[1] Published chiefly in Virchow's Archiv.
[2] Zeitschrift f. klin. Medicin, Bd. xv., Hfts. 1 u. 2.
[3] Virchow's Archiv, Bd. cix.

ever, may simply mean that the spirilli, most of which gradually disappear from the blood at the crisis, have lived their life and are about to die, and in this state are taken up by the normal splenic phagocytes, just as are the effete red blood-corpuscles. He explains the recurrence of the second, or even of the third attack, of the fever by supposing that certain spirilli remain alive after the crisis and start afresh a new generation, which is not retarded in its growth, as the phagocytes are too busy in digesting the spirilli which they have eaten during the former attack.

An interesting study of phagocytosis has been made by Daehr,[1] a pupil of Ribbert, who has studied the effect of injection into the lungs of rabbits, through the trachea, of staphylococcus pyogenes aureus. Within a few hours the cocci are almost all to be seen within the alveolar epithelium, and in the leucocytes, which latter, in the course of a few days, disappear from the alveoli and pass into the bronchi. Meanwhile, the alveolar epithelium proliferates, causing a catarrhal inflammation. Within the first week the cells contain many cocci, which gradually become less numerous, and in the second week entirely disappear. He looks upon this as a confirmation of Metschnikoff's views.

In a second investigation, Hess[2] has studied, in rabbits and cats, the relation of the leucocytes to the staphylococcus aureus inoculated in the cornea. At first there is marked increase, which leads to an acute inflammatory process in the neighborhood of the cocci. The leucocytes increase rapidly, and within two or three days almost all of the cocci are within cells. In cases which recover, by the sixth day no cocci are found. When the process does not result in healing, the phagocytosis is slight.

Baumgarten[3] states that experiments made in his laboratory do not confirm these results of Hess.

Ribbert, in his study on the destruction of pathogenic bacteria in the body,[4] supports Metschnikoff's views. He found, after injection of the spores of aspergillus and mucor, that they collected in the organs of the experimental animals, particularly in the liver and lungs, and that within a few hours after injection they were surrounded by leucocytes, which either completely prevented or restricted the growth of the germs. Injections in very large quantities might not be sufficient to hinder the growth of the parasites, and the animal died. In the lungs and in the liver the phagocytes are much more active than in the kidneys. Precisely similar occurrences were found where the spores were injected into the anterior chamber, and it is worthy of note that he found on the anterior surface of the iris, in the neighborhood of the pupil, the phagocytes much more active and the disintegration of the spores much more marked than in the posterior part of the iris in contact with the lens. Ribbert holds that the destructive influence of the leucocytes is exercised chiefly by their preventing access of nourishment to the spores (particularly of oxygen), and in favoring, also, an accumulation about them of destructive metabolic products. He regards the fixed connective-tissue cells of the liver, and the giant-cells which develop in the liver and in the lungs, as the most important agents in the final destruction of the spores.

As we might suppose, the views of Metschnikoff have met with sharp criticism in many quarters, and from no one more ably or at greater length than from Baumgarten.[5] While not denying that the leucocytes eat the bacteria, he claims that the process is by no means universal, and is carried on so unequally that we can scarcely speak of an active warfare waged against the parasites.

As a specially weak point, he alludes to the powerlessness of the phagocytes in the daphnia disease so soon as the conidia are formed from the spores.

In relapsing fever, the freedom from attack which the spirilli enjoy in the blood is urged strongly against the phagocytic theory. The fact that spirilli are found in a number of cells of the spleen toward the crisis simply means that the phagocytes of this organ behave to them as to other foreign bodies. Probably, too, the spirilli begin at this time to lose their vitality, as is shown by their less active movements, and are then readily taken up by the splenic leucocytes in a manner precisely similar to effete blood-corpuscles.

In erysipelas, Baumgarten criticises the position in which Metschnikoff finds the parasites, namely, in the second zone, behind the advancing cocci, as conclusively showing that they are not fighters of the battle—not, as he expresses it, "the heroes of the day, but the hyenas of the field."

The observations of Christmas-Derkinck-Holmfeld[1] are also directly opposed to the theory of phagocytosis. He finds in anthrax experiments that very few of the bacilli are taken up by the leucocytes. In rats they degenerate within two or three days after inoculation, and for the most part outside of the cells. He holds that pus-formation is a conservative reaction against the penetration of the bacterial germs, but that the neutralization of the action of micro-organisms depends much more on the chemico-biological relations of the tissues than on any property of the cells to destroy them by inclusion. His view, in fact, approaches that of Ribbert, already referred to, in ascribing the limitation of bacterial growth to nutritive changes, particularly to the restriction of oxygen, rather than to any phagocytic action of the cells.

In Flügge's laboratory, observations have been made by Bitter and by Nuttall,[2] of San Francisco, which directly contradict those of Metschnikoff. Nuttall's elaborate experiments appear to show conclusively that the destruction of the bacilli in the living body is not effected by the phagocytic action alone.

And, lastly, in tuberculosis, the question of the relation of the cells to the bacilli is being carefully studied. In his recent paper on the subject,[3] Metschnikoff claims that the degeneration of the bacilli, which has long been known to occur within the giant-cells, results directly from their phagocytic action, and is not a natural decay. Baumgarten, on the other hand, regards the relation of the giant-cells to the bacilli as one of the strongest evidences against the theory of phagocytosis.

With the relations of phagocytes to bacteria, I have had so little practical experience that I hesitate to express any positive conviction on the question; but I have, for nearly three years, been working at a problem identical in all its relations, but in which the parasitic bodies belong to a higher class of organisms. I refer to malaria, and to the hæmatozoa which occur in the blood of this disease. A sceptical attitude in these days of hasty observation and of still hastier conclusions is peculiarly appropriate. I complain of no one who, without ample opportunities for personal study, claims the right to question the full significance of Laveran's important discoveries. Perhaps, better than anyone else, I am in a position to extend sympathy to the sceptic, as, until ample material came to hand in 1886, I was among those who looked upon the work of Laveran with extreme incredulity. The corroboration, in almost every detail, which his studies have received during the past three years is in all respects remarkable. Working as he did, alone in Algiers, under circumstances the reverse of favorable, without proper laboratory equipment, without the stimulus to be found in the association of men in large cities, it is not only in the highest degree creditable, but most encouraging, that an army surgeon, actively engaged in the duties pertaining to his battalion, could accomplish so thorough a piece of work, requiring but little subsequent correction, and receiving at all hands ample confirmation.

Richard, in France; Marchiafava and Celli, Golgi and his pupils, in Italy; Sternberg, Councilman, James, Shattuck, and myself, in this country; and Vandyke Carter, in India, working far apart, have all practically confirmed, with minor modifications and amplifications, Laveran's observations.

While the invariable association of these parasites with malaria would appear to be settled, their precise morphological relations are still a matter of discussion. I have urged, from their resemblance to other hæmatozoa, that they should be classed with the genus of Hæmatomonas (Metrophanow), which includes all forms of monads parasitic in the blood, of which a considerable number is known among the lower animals. Briefly, to refresh your memory, I may refer to the forms which occur in ordinary malaria. In the acute cases there exist in the red blood-corpuscles hyaline and pigmented bodies which undergo amœboid changes, and which gradually destroy the corpuscles, converting the hæmaglobin into a black pigment. Under certain circumstances, more particularly during the paroxysms, these bodies increase in size and undergo segmentation, breaking up into a number of small, free spherical bodies. In smaller numbers in the blood, but more constantly in the spleen, are the remarkable flagellate organisms. Lastly, in more chronic cases there are the still more extraordinary crescentic forms. Practically, the unanimity which exists in the statements of the observers above named regarding these bodies, places the question of their existence in malaria (and I may say, based upon the number of negative observations, in malaria only) beyond any reasonable doubt.

That they truly constitute the actual germ of the disease is, however, a point upon which opinions may differ. The constancy of their presence, their absence in other individuals in malarial regions, their abundance in the graver forms of disease, the destructive influence they exert upon the blood-corpuscles, are urged by Laveran in evidence of their pathogenic nature.

However this may be, the question which here concerns us relates to the relation between the phagocytes and these bodies. Surely one might suppose that here, if anywhere, the theory of phagocytosis might receive confirmation or rebuttal. What but phagocytes are the amœboid forms of these parasites which exist in the red blood-corpuscles, gradually destroying the stroma and the hæmoglobin until nothing but a shell remains? Here, indeed, are foemen worthy of the steel, or, rather, of the plasma, of the leucocytes. What, then, are the facts? How far can we say that in the blood in malaria, the seat most assuredly of the chief pathological changes, in acute cases, that there are evidences of a struggle between the phagocytes and the hæmatozoa. It has long been known that the leucocytes in this disease (particularly in chronic cases) contain pigment granules. There is no other affection in which melanæmia is so constant a feature, though it is now and then met with in other conditions. The leucocytes obtain the pigment either in the blood itself, or in the liver, spleen, or marrow, where the red corpuscles undergo their final destructive changes. In an examination of nearly one hundred and fifty cases of all forms of malarial affections, I have looked carefully at this point with a view of determining the exact mode in which the leucocytes obtain their pigment, and in my observations of the past two years the question of their relation to the various forms of the hæmatozoa has engaged my special attention. It may be remarked, in the first place, that there is certainly an increase in the number of white blood-corpuscles, an increase not associated, so far as I know, with any special change in the character of these bodies.

The result of my work in this direction may be stated in a few words. In the blood, at least, there is very slight evidence of the existence of phagocytosis. Here and there, it is true, we meet with leucocytes which have included the amœboid forms of the parasite, either free or still surrounded with the shell of a red blood-corpuscle. I have but three or four sketches in a whole series illustrating this fact. Occasionally a crescent may be seen within the white blood-corpuscle, more frequently the smaller free bodies which result from the segmentation. I have, in my paper on this subject, given a sketch of a leucocyte which was watched for an hour and a half, and had included one pigment body, and was about to take a second, behaving identically, though more deliberately, than its great prototype, the pond amœboid. I confess myself disappointed in this respect. It may be urged that in a blood drop, after withdrawal, the conditions are not favorable for study. But the absence of any great number of leucocytes, containing parasites, in a comparatively unaltered state, show that certainly in the circulating blood the leucocytes do not actively attack and eat the parasites. More probably, I think, they pick up the pigment granule after the disintegration of the parasite, or in such regions of the circulation as the spleen or the bone marrow where the conditions are more favorable to phagocytic action. Even on the warm stage, with the leucocytes displaying for hours amœboid movements, and in specimens which contained "foes" innumerable, it was exceptional to see evidence of active warfare.

It is, of course, more difficult to obtain evidence of the relation of the supposed contestants in the spleen, liver, and marrow, the organs in which regressive and progressive blood changes are constantly going on. I have not myself practised puncture of the spleen in these cases, as has been done extensively by Councilman. Fatal cases of malaria are not now very common. I have only had opportunities of examining two, both of chronic paludal cachexia, the result of prolonged exposure in Panama. One, an old man, admitted under my colleague, Dr. Musser, whose blood presented many of the characteristic forms; the other, a profoundly anæmic man, with a greatly enlarged spleen, but in whose blood very few of the parasites were found. In both instances the liver, spleen, and bone marrow showed characteristic melanotic changes. In the spleen the pigment in various shades, from brown to deep black, was chiefly in the thickened trabecular tissues and about the vessels. Teazed portions showed:

(1) Large numbers of leucocytes containing brownish-black pigment grains. A few of the leucocytes contained the small amœboid forms which had been noticed to be very abundant during life.

(2) Larger cells, containing red blood-corpuscles in all stages of degeneration. These cells were of various sizes, and contained a variable number of corpuscles, from eight to ten, or even more. Some of the red corpuscles contained amœboid parasites, but by far the larger portion of them presented the usual appearance met with in cells of this character in the spleen.

(3) Large, irregular, flattened cells, probably derived from the epithelium of the spleen capillaries, which contained granular black pigment, and occasionally red blood-corpuscles.

(4) Spindle or branch cells of the reticular tissue enclosing brownish or black pigment grains.

(5) Free pigment.

Practically the condition was similar, though more extensive in degree, to that met with in this organ, and in other febrile states associated with extensive blood destruction. I really could not say that the splenic phagocytes exercised any selective power in picking out for attack those corpuscles which contained parasites or crescentic forms, which in one of these cases existed in considerable numbers. The bone marrow in both cases presented microscopic changes characteristic of the lymphoid tissue, and had a grayish-brown color, due to excess of pigment. There were in it, in large numbers, marrow cells and ordinary leucocytes containing irregular pigment, and occasionally free amœboid forms of the parasites. The cells containing red blood-corpuscles were very abundant; but here, as in the spleen, it was partic-

ularly noted that the red corpuscles not containing the parasites were as frequently, or even more frequently, enclosed in the cells. In the liver the pigment existed in three elements:

1. In leucocytes, which seemed numerous in the lobular capillaries, particularly at the periphery.

2. In the walls of the capillaries, in all probability in the endothelial cells.

3. In the stroma cells, particularly of the interlobular tissue about the portal canals, where in places it was sufficiently abundant to cause ordinary diffuse pigmentation, a part of which was due to grains lying free in the interstices of the tissue.

Metschnikoff states that in malaria the parasites are attacked chiefly in the spleen and the liver by the larger phagocytes existing in these organs, and to a much less extent by the leucocytes in the circulating blood.

We see, then, in malaria very little evidence in the blood favoring a theory of phagocytosis; certainly no such campaigning on the part of the leucocytes as might be expected from the presence, in such numbers, of foes so destructive to the red corpuscles. In the spleen, bone marrow, and liver, the organs in which the dead or dying blood-disks are normally cremated, to use Weigert's expression, we have, as might be expected, an activity proportionate to the increased amount of material to be consumed, but scarcely such heightened phagocytic action as would indicate, on the part of the leucocytes, an aggressive warfare.

Into the interesting theory that to the action of phagocytes is due the immunity against certain diseases or against a second attack, I cannot now enter. In the present unsettled state of our knowledge it would be premature.

To conclude: While phagocytosis is a widespread and important physiological process throughout the animal kingdom, and while it undoubtedly plays a most important part in many pathological conditions, the question of an active destructive warfare waged by the body-cells against the micro-organisms of disease must still be considered an open one.

A British View of What the Profession Needs.—A correspondent of *The Lancet* writes as follows, under the caption of "The Protection of the Medical Profession:" "I quite agree with Dr. H—— that we want more *unanimity*, but the unanimity we want never has come, and I fear never will. We want the unanimity that will prevent twenty men rushing after an appointment which another man resigns because it does not pay. We want the unanimity that will prevent one man poaching on another man's manor. We want the unanimity that will prevent a man openly accusing his neighbor of improperly treating a case. We want the unanimity that will prevent a man with some means settling in another man's district where there is no scope, and by *underbidding* try to obtain patients from brother-practitioners who have bought old-standing practices. We want the unanimity that will prevent men from charging 4d. and 6d. for a bottle of medicine, 1s. for a visit, and touting for confinements at 5s. and 7s. 6d. each. If this unanimity could be obtained we should be quite able to protect ourselves. We could then be fairly remunerated for our services, and more respected. As it is, the public know our weak points, our readiness to work at any price or no price, and make fools of us accordingly. If, in the words of the poet, we could all realize that

> "'In fortune and in fame we're bound
> By stronger links than steel,
> And neither can be safe or sound
> But in each other's weal,'

the 'discordant units' might then be 'consolidated into one harmonious whole.' But when will that happy period arrive?" [A little of this unanimity appears to be needed at home as well as in England.—Ed.]

CHRONIC INTERMITTENT FEVER OF SEVERE TYPE AND UNKNOWN ORIGIN.[1]

By GEORGE L. PEABODY, M.D.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; ATTENDING PHYSICIAN TO THE NEW YORK AND ST. LUKE'S HOSPITALS.

So far as I am aware medical literature contains but few cases at all resembling the one which I shall report this evening.

In 1887 Ebstein[2] reported a somewhat similar case under the title "Chronic Relapsing Fever, a New Infectious Disease." His patient was a delicate man, nineteen years of age, without hereditary taint, who had suffered for a long time from recurring attacks of fever in such a manner that periods of fever and of apyrexia alternated with a certain degree of regularity. In two hundred and eleven days the patient withstood nine such attacks of fever, each of which lasted thirteen or fourteen days, and during this time the periods of apyrexia averaged ten or eleven days in duration. In the attacks the temperature rose abruptly to 104°–105° + F., and then subsequently fell equally abruptly to the normal.

In this case, in which he says this fever had then run a tedious course of nearly a year, absolutely no complications developed, so that the course of the temperature was regarded by him as the sole symptom of importance. There was no delirium. The heart was very feeble. The examination of the blood revealed nothing abnormal. The digestive apparatus manifested the usual symptoms of fever. During the attacks the spleen was always swollen, but it always became normal in size again after their subsidence. The superficial lymph-glands were never enlarged. The attacks of fever could not be prevented by any treatment, such as the administration of quinine or arsenic.

Later in the same year, in the same journal,[3] Ebstein published the results of the autopsy of his patient, who, it seems, died after the eleventh attack, in coma, bed-sores and œdema having previously aggravated his condition. At the autopsy hard malignant lymphomata were found in the bronchial glands, and also in the mediastinal and retroperitoneal glands, as well as in the lungs, pleura, and liver. Infarctions were found in the kidneys and spleen. Fatty degeneration was present in the myocardium and in the muscles of the trunk, as well as in kidneys and liver. Thus the anatomical picture of pseudo-leukæmia, or Hodgkin's disease, seems to have been portrayed. He considers that his first title was well chosen as describing the disease, and thinks it proper to distinguish such cases from pseudo-leukæmia. No specific micro-organism was found to account for the disease, and he had no reason to suspect that it bore any relation to syphilis.

In the same journal[4] P. K. Pel, of Amsterdam, under the title "Symptomatology of so-called Pseudo leukæmia," describes a somewhat similar case. His patient was a man, aged twenty-five, who was under observation about four months. His symptoms suggested the presence of long-continued typhoid fever, in that his spleen was enlarged and in that his fever presented the peculiarity of frequent abrupt elevations of temperature following indulgence in solid food. Pel's case lasted from June 1 to October 6, 1884. It began very like a typhoid fever, with chilliness, nausea, dry cough, and pains in the abdomen. His periods of fever varied from a few days to two months in duration, and his periods of apyrexia varied from one to two weeks in duration. Throughout the illness the fever was the chief symptom. I am able to show you the temperature-chart, which gives the course of this

---

[1] Read at a meeting of the Practitioners' Society, March 1, 1889.

[3] Loc. cit., No. 45.
[4] Loc. cit., 1885, No. 1.

patient's fever. The autopsy revealed a large spleen, very general enlargement of the mesenteric, retroperitoneal, and bronchial glands, but no involvement of the superficial lymph-glands whatever.

We will all admit that these were very puzzling cases. Whether the patient whose history I will now proceed to narrate to you belongs in the same category, only the autopsy, which is not likely soon to occur, can possibly determine.

My patient is a well-developed Danish girl, seventeen years of age, who entered the New York Hospital, April 14, 1888. For the history of this patient I am indebted to the kindness of Dr. G. H. Cobb of the house-staff. From his voluminous notes I have prepared my report of the case.

She was unmarried, and a servant by occupation. From her mother it was learned that the girl's father had died of "lung disease," and that the patient, when twelve years of age, had been very ill with "kidney disease," in the hospital at Copenhagen. At that time her most prominent symptoms seem to have been œdema of all the extremities, palpitation of the heart, and dyspnœa. As these symptoms began to pass away the child began to menstruate. This illness was not a complication of scarlet fever, diphtheria, or any acute infectious disease.

From that time to the present time, *i.e.*, for five years, she has had frequent attacks of high fever, without assignable cause, accompanied by very rapid and shallow respiration. These febrile attacks have been most marked during the days preceding the menstrual epochs, though they have not been confined to those times.

There has not been emaciation, and there has been but slight impairment of the general strength. Appetite has been fair throughout the entire time, and the general condition has been excellent.

Two years ago another similar illness was of such severity that the patient was again an inmate of the Copenhagen hospital. At that time severe headache, fever of varying intensity, anorexia, nausea and vomiting of daily occurrence, and constipation were the only well-marked symptoms.

This second severe illness was of six months' duration. She recovered completely, and subsequently came to this country. After eighteen months of comparative health she was admitted to the New York Hospital, April 14, 1888. She stated that for "some time" she had suffered from headache, vertigo, tinnitus aurium, palpitation, and occasional œdema of the feet. Four days prior to her admission she had had much abdominal pain in the neighborhood of the umbilicus, anorexia, frequent vomiting, and one slight hæmatemesis. She was constipated. When admitted her temperature was nearly 103° F., her respiration 66, and shallow, and her pulse 126. She suffered constantly from thirst.

A careful examination revealed no thoracic, hepatic, or splenic lesion. Her abdomen was distended and tympanitic. There was tenderness on pressure in the lower portion of the epigastric region, in the upper portion of the umbilical region, and, to a less marked degree, in the right inguinal region. There was no tumefaction to be felt anywhere, resonance was everywhere normal, the thighs were not flexed, the tongue was coated, the pulse was full and soft. The course of the temperature can best be shown by the accompanying chart.

In consequence of the fever, tenderness, and pain, as well as of slight resistance in the right inguinal region, it was thought that she might be suffering from perityphlitis. A vaginal examination revealed a sense of fulness in the right parametrium and posterior fornix, which seemed to be due to the presence of a soft mass in that situation which easily yielded to pressure. The uterus was freely movable.

Her temperature continued constantly elevated, as you see by the chart, for more than a week, and then there seemed to be felt by abdominal palpation a sense of deep resistance in the region between the right iliac fossa and the umbilicus. Soon pressure in this situation became decidedly painful.

The examination of her urine, which had been made immediately after her admission to the hospital, revealed nothing abnormal beyond the usual indications of fever. Inasmuch as the local abdominal symptoms continued, on April 22d she was etherized and operated upon for a supposed perityphlitic abscess. No abscess was found, but the vermiform appendix was found partly embedded in a mass whose appearance suggested the possibility of it being an enlarged lymphatic gland. This mass measured 2½ by 3 inches by 1 inch. No other abnormality was discovered.

She reacted well after the operation, but needed stimulants for a few days, owing to the fact that her heart seemed feeble.

Her urine continued normal in all respects, except that for a few days its quantity was only ʒ xx. per diem.

Her bowels were easily moved by laxative enemata, which were administered every other day.

Two weeks after the operation the abdominal wound had entirely healed, and her general condition was excellent.

For ten days following the operation the temperature had been but little above normal; but on the 4th and 5th of May it rose to the neighborhood of 102° and 103° F., respectively, without apparent cause. At this time she was given quinine, gr. v., three times a day, following which the fever seemed to abate distinctly, but only temporarily. Ten days later, during menstruation, the fever again appeared, presenting the picture of abrupt sudden elevation of temperature, usually in the afternoon or night, but occasionally in the morning.

At the time of this, the first menstrual epoch which occurred after she came under observation, she became quite emotional, and manifested an hysterical condition of mild grade. Respirations were very rapid, the face would flush deeply and frequently, and there were areas of anæsthesia in the upper extremities.

Her urine continued normal, she ate solid food freely, and her general condition was excellent, although for the next two weeks her temperature was rarely normal, and was often between 102° and 105° F. The rapid rise and fall remained characteristic. Every precaution was taken against possible deception on her part, the temperature being frequently taken simultaneously under the tongue, in the axilla, and in the rectum.

From May 13th until her discharge from the hospital, on August 24th, she was rarely twenty-four hours without fever. Her temperature was frequently normal once a day, but it rarely remained so, and it often rose as high as 104° F. and higher.

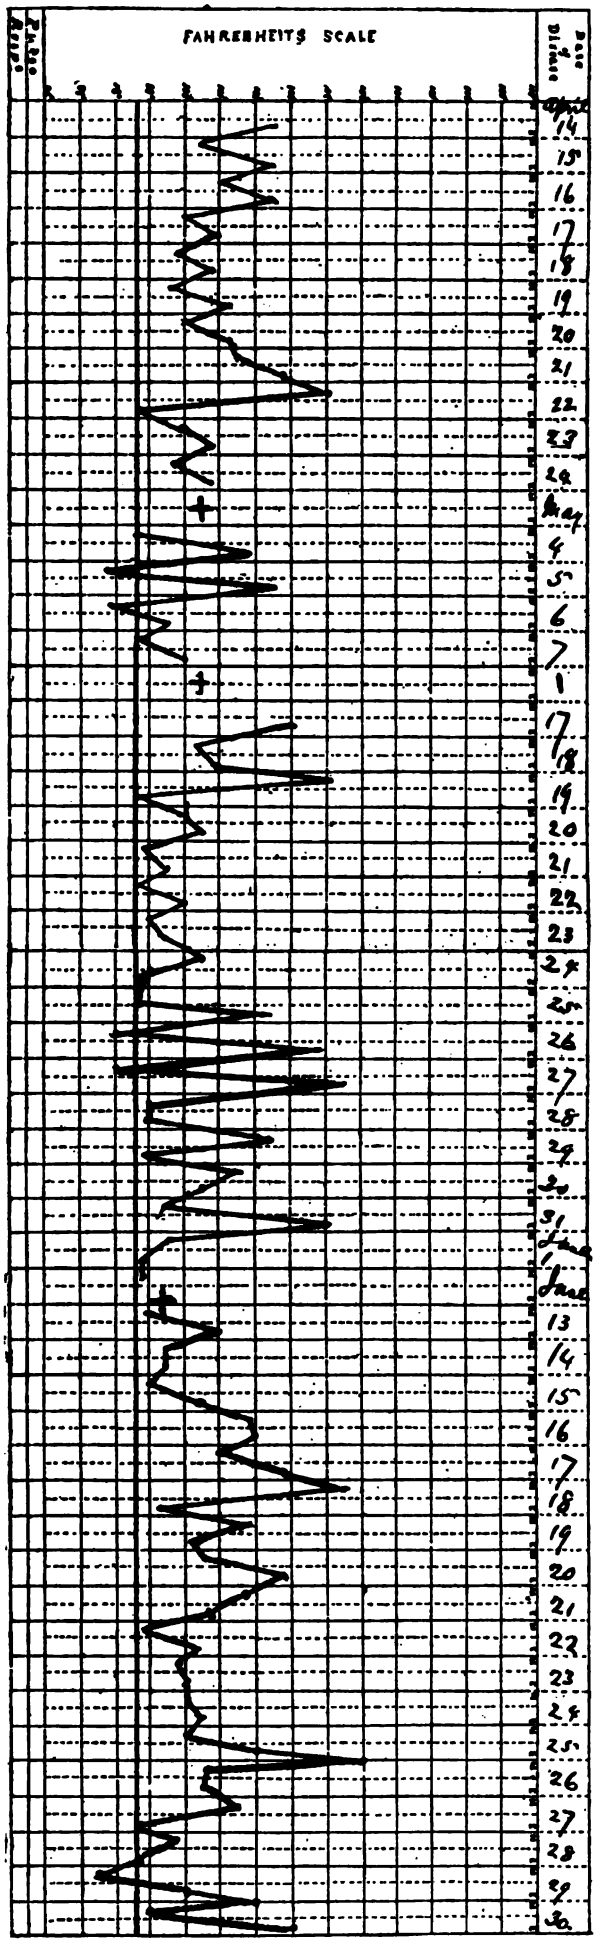
During much of this time she was up and about, feeling well and making no complaint, and occasionally out of the hospital for several consecutive hours. She was frequently given tonics, laxatives, and various antipyretics. She did not lose weight. When the sudden rise of temperature occurred her pulse would often become very rapid, and her respiration shallow and frequent. Occasionally it was noted that œdema of the legs, more especially of the left leg, developed after she had been moving about much, and once in a while albumen would appear in her urine, but never any casts.

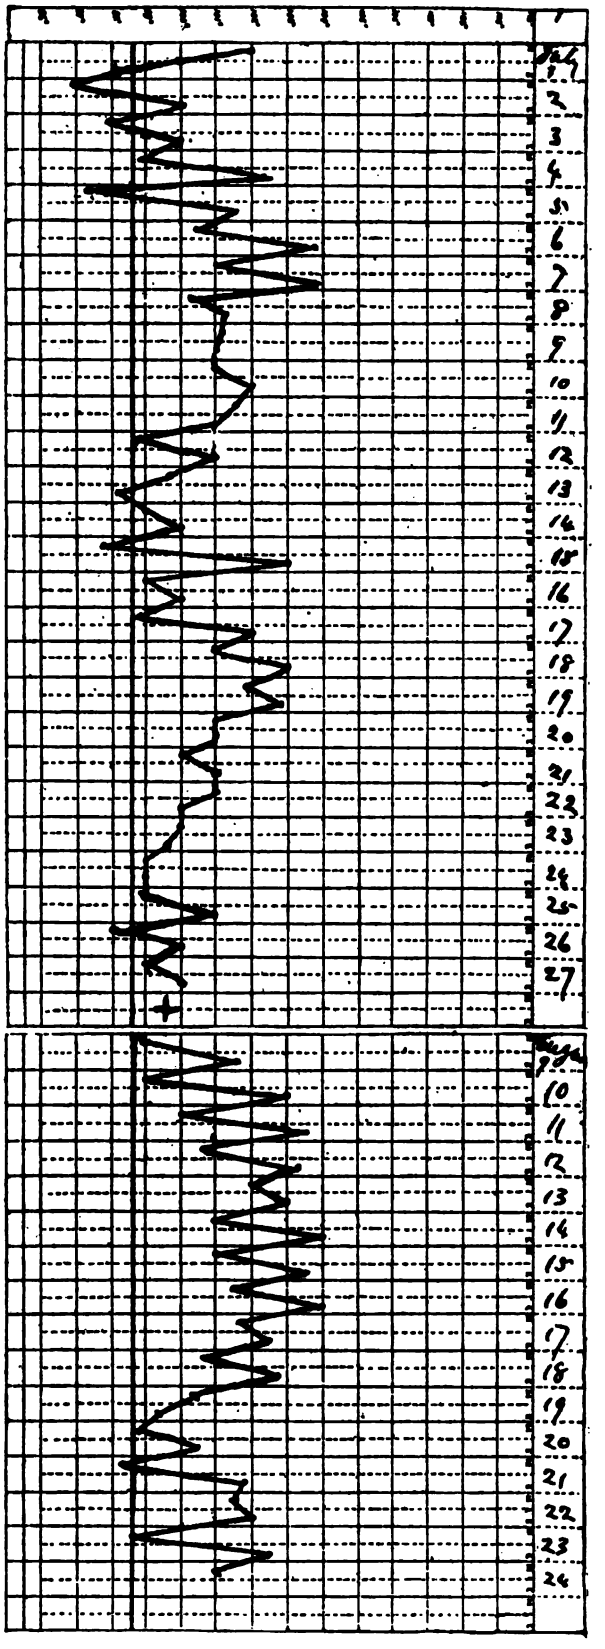
Careful examinations of her blood were made from time to time. The hæmoglobin was always deficient, but there were no other abnormalities at any time, such as micro-organisms, or disturbed relation in the number of the cellular elements. Notably there was never any excess in the number of white cells.

At her own request she was discharged from the hospital, August 24th.

On November 12, 1888, she applied again for admission.

She then stated that she had been in only fair health since leaving the hospital; that she had continued to suffer

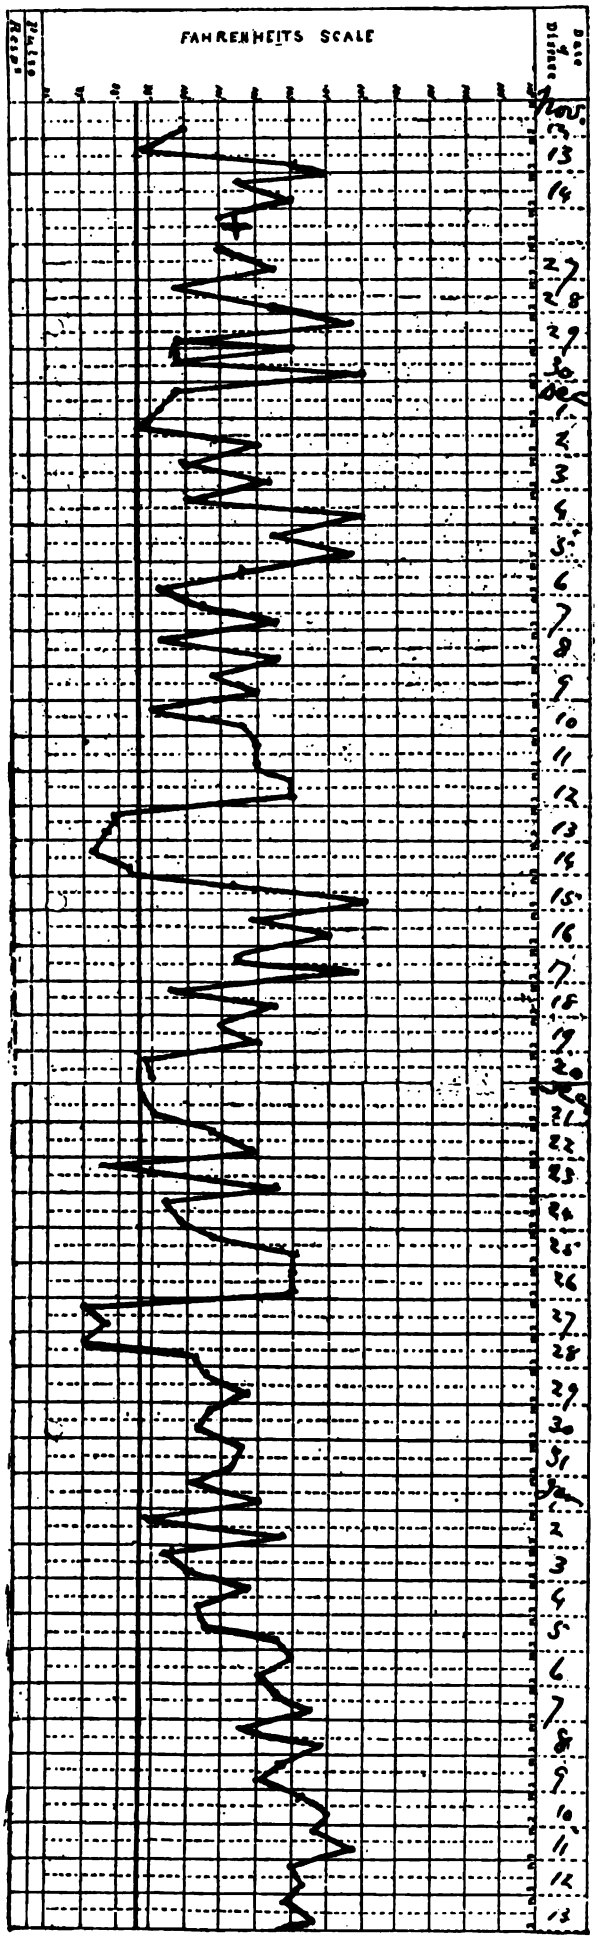


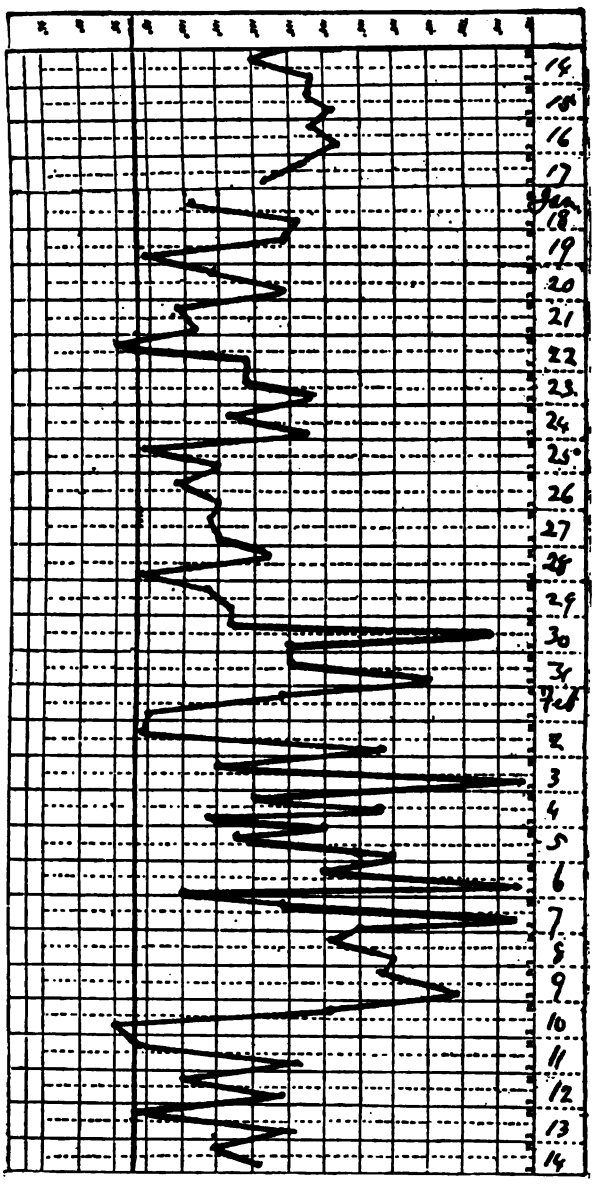


from occasional attacks of fever and headache, with fugitive and not severe precordial pains, and œdema of both feet and legs, more especially of the left.

A very careful examination revealed no thoracic or abdominal lesion. The day after her admission her temperature rose to 104° F., and she was put upon arsenious acid.

A careful microscopic examination of her fæces was now made, with the result only of ascertaining that there was rather an unusual amount of fat present in them. It occurred to me that possibly intestinal parasites might be





causing a certain amount of peripheral irritation, which might account for some of her symptoms; but I failed to find any evidence of their presence in the fæces. Her urine was normal in every respect, except as to the ordinary evidences of fever in it. There was no reaction to Ehrlich's test. She was still in excellent general condition. Up to the middle of December, or for a whole month after her readmission, her temperature was normal very rarely, being usually between 100° and 105° F. Frequently the vaginal temperature, as might be expected after eating or drinking, was several degrees higher than the mouth temperature.

Early in January she had an attack of pharyngitis, and after this her temperature rose rather higher and remained rather more continuously elevated than before. For more than a week now it rarely went as low as 102° F., and was frequently over 104° F.

During the latter part of January she felt well enough to be up. On January 30th, at noon, she had a chill, after which her temperature rose to 108.6° F.. Later in the day three other chills occurred.

The next afternoon and evening she had repeated chills, and her temperature, which the day before had fallen as abruptly as it had risen, rose to 106° F.

During the next week chills occurred frequently and irregularly, often several times a day, and always with rapid rise of temperature. On one occasion it nearly reached 109° F., and on another, 110° F. There was but very slight difference between rectal and mouth temperature on these occasions.

I have rarely seen such severe chills as this girl had on these occasions. The entire bedstead was shaken, and her whole face became cyanotic.

The blood was again repeatedly examined for malarial or other organisms, with negative result.

The surface temperature, in various parts, would often be normal when the rectal temperature was 104° F.

On February 5th she had a chill at 6.30 P.M., after which her pulse, respiration, and temperature were, respectively, 156, 56, and 108° F. This was soon followed by a severe convulsion, during which she did not lose consciousness, and which bore many resemblances to an hysterical attack.

In this convulsion the pupils were equally dilated, and reacted to light. There was no ocular deviation. Face was not drawn to either side. Tongue was not bitten. There was no frothing at the mouth. Cervical muscles were in a state of tonic contraction; forearms were flexed on arms, and both arms drawn toward median line of body; hands were flexed on wrists; fingers extended; thumbs flexed. There was no fibrillary contraction of any muscles. Legs were flexed on thighs, but were extended by patient when she was told to do so. Hands and arms were plastic, being easily changed in position, and remaining as they were placed. Convulsions, later during the week, were of same character, and none were more pronounced than this.

On the next day there occurred another chill at 2.30 P.M., which lasted twenty-five minutes. After this the temperature rose to 107.4° F. At 7.45 on the same evening another chill was followed by a temperature of 109.2° F.

On February 7th and 8th chills recurred, each time with high fever. A careful record of her weight had been kept, and it was now found that she had lost seven pounds since her return to the hospital.

On February 8th the actual cautery was applied freely on both sides of the spinal column. After this her temperature in a few days rose once as high as 107° F., but thereafter, as the chart shows, it slowly declined, with occasional marked fluctuations, until the 21st, since which date it has never been above 100° F.

By the 22d it was found that she had regained six of the seven pounds of weight found to have been lost only two weeks before. When the temperature was very high, occasional doses of phenacetine were administered.

About the middle of February she suffered somewhat from a carious tooth, which was subsequently extracted.

After the cauterization of the back the cautery was left beside the patient's bed, with the understanding that it would be immediately applied if any convulsive seizures came on again. She was also told that she would be moved to an isolating room and shut up there, if they should recur.

On February 10th the head-nurse of the ward, who had been absent since January 30th, returned, and under her restraining influence two seizures were aborted on the 12th. The ward had been in confusion during her absence, and with her return and the general quiet which followed, the patient seemed to improve rapidly. It is to be noted, however, that the chills, and very high temperatures following them, began in the previous month before this excellent nurse had left the ward.

Nothing worthy of note has since occurred to her, except that, during the intensity of toothache, temperature, respiration, and pulse were all lower than before. Also, during the height of her fever the patient gained in weight. Examination of the urine on three occasions showed that it contained 14.4 gr. of urea to the ounce.

She has now been under observation nearly eight months, and during that time she has rarely been as long as a week without fever until quite recently. No treatment has seemed to affect the course of the temperature, unless the recent application of the cautery has done so, and the nature of the cause is still enshrouded in doubt. Her fever has, at times, been of very unusually high grade, and nevertheless her nutrition has not appreciably suffered, except temporarily.

The pulse and respiration were often extremely frequent.

I have but little to add in the way of comment in submitting this case to you for discussion. Under the impression that ague might be the cause of her symptoms, quinine and arsenic were faithfully tried, without result, and blood-examinations were always negative. Her general treatment has been tonic and sustaining.

That an element of hysteria exists in the girl no one can question; but whether that is more likely to be a cause or a consequence of her other symptoms remains with me a matter of doubt.

That I may have to do with a case of pseudo-leukæmia I feel well aware, and yet many of the manifestations that I have described to you, such as chills and convulsions, with phenomenally high fever, can hardly be said to apply to that condition. It seems to me that her case is either a combination of hysteria with pseudo-leukæmia, the latter running a very unusual course, or else she is suffering from a hitherto undescribed chronic infectious disease.

Two or three years is the usual maximum duration of pseudo-leukæmia, whereas this one has lasted six. Besides, there is no enlargement of spleen, or any superficial lymphatic glands. Her abdomen is flaccid, and deep palpation fails to reveal the presence of enlarged retro-peritoneal glands. On the other hand, at the surgical operation, at which I was not present, the vermiform appendix was seen to be partially embedded in what looked like an enlarged lymph-gland.

The vaginal examination, again made last week, revealed nothing abnormal.

SUSPENSION-TREATMENT OF LOCOMOTOR ATAXIA AND OTHER DISEASES OF THE NERVOUS SYSTEM, WITH REMARKS AND AN ILLUSTRATIVE CASE.

By WILLIAM J. MORTON, M.D.,

NEW YORK CITY.

Le Progrès Medical of January 16, 1889, containing a striking announcement by Professor Charcot concerning the treatment of locomotor ataxia, and incidentally of some other nerve-affections, by suspension of the body of the patient, reached this side of the water promptly, and the method outlined was immediately put in practice by the writer, and doubtless by other physicians, since anything which offered even a moderate relief to this class of incurables could not fail to attract close attention.

Little, if anything, upon this subject has up to this time appeared in our current medical literature, and it therefore appears to me, after a continued experience of over two hundred suspension-treatments in a considerable number of cases, to be a proper time to venture a few remarks upon this new treatment and the method and apparatus employed, recording at the same time from among those treated a single and by no means exceptional case illustrative of what may be accomplished, in the hope that others who may have given the subject attention will publish their views. It may fairly be assumed that a considerable literature will spring up in the wake of the entry of this recent phase of nerve-stretching into the medical practice of the day.

For Charcot's announcement and results embody, in a practical manner, and apply to the spinal cord that idea of stretching or elongating individual nerves which has been groping its way in a variety of forms into general practice during nearly two decades, beginning with Nussbaum in 1872 for the relief of contractions—some years later extended to the surgical stretching of the sciatics in locomotor ataxia by Langenbeck, and still later more popularly assuming the form of "bloodless stretching" or elongation by passive movements. The operation, surgical or non-surgical, has been extended to a great

variety of morbid nerve-conditions and diseases and with results in many of them which have far surpassed those before obtained by other means in similar cases.

But while the surgical operation was the most effective, it could not in the nature of things be frequently repeated on the same nerve, and while the passive movement could be frequently repeated it was not equally effective. Another step remained to be taken, and that we now seem to have reached in suspension. And favorable as has been, on the whole, the history of individual nerve-stretching, no contribution to the subject in general, in the opinion of the writer, has equalled in importance this most recent procedure.

Professor Charcot states that the idea of this treatment belongs to Dr. Motchoukowsky, of Odessa, who published it in 1883 in a brochure which has, up to this time, attracted little attention, and that in his brochure Dr. Motchoukowsky speaks of having treated, and considerably ameliorated, twelve tabetics, at the same time re-establishing, by the same operative procedure, the sexual functions of other patients suffering from impotence of nervous origin, independent of tabes. The treatment consists in the suspension of the patient during a period varying from one to four minutes, by means of the apparatus so effectively arranged by Dr. Sayre, of this city, for the rectification of deformities of the vertebral column while applying his plaster jacket.

The results[1] arrived at at the Hospital of La Salpêtrière, under Charcot's general supervision, may be briefly summarized as follows:

The suspensions take place every other day, this seeming to give better results than if repeated daily. Their duration is progressive. At first one-half minute, and increased by one-half minute daily until, as has been said, a maximum of four minutes is reached. During suspension the arms should be frequently raised, that the traction upon the vertebral column may be increased.

Eighteen tabetics had been treated by a total of about four hundred suspensions. Of these four are omitted from consideration because of not having been treated but three times, owing to their inability to reach the hospital. The fourteen others experienced an improvement which, with eight in particular, was altogether remarkable.

At the beginning of treatment the improvement first appeared in the gait and in the power of co-ordination. The patients walked better after each suspension, and this effect, while at first only of a few hours' duration, after eight or ten treatments became continuous. The patients stood erect more easily, and walked greater distances with more ease. After twenty to thirty treatments the swaying disappeared, and the vesical troubles improved. The shooting pains became less frequent, and in some cases ceased. Where complete impotence existed the sexual power became restored. Numbness of the feet and plantar anæsthesia disappeared. In conclusion, all the patients treated improved in different degrees and the improvement appeared to be in direct relation with the duration of treatment.

The cases of locomotor ataxia that I have thus far treated by this method are six in number, submitted to over two hundred suspensions, and all occurring in private practice—a number small as compared with that which may be easily got together in hospitals and dispensaries, and not sufficient to justify any permanent conclusions, but sufficient on the other hand to carry the conviction to my own mind that by no other means has equally marked, progressive, and decided improvement been attained. My experience leads me to confirm in every particular the results observed in the eighteen cases at La Salpêtrière. But as it is not my purpose at this moment to record these cases, since the treatment has not yet been sufficiently long continued, I will content myself with the brief record, so far as it has advanced, of one case which offers perhaps more striking points than any of the others.

Thomas H——, Morristown, N. J., aged thirty-five, married. February 28, 1889. Entered office with extreme difficulty, using two canes and with his eyes closely watching his feet to prevent falling. Falls at once even with canes unless he can *see* his feet. He had previously visited me in November, 1886, on account of "rheumatic pains in the legs" and "trouble with his eyesight." The pains I found to be sciatic, of a mild type, and as to his eyesight, the obvious feature was a pronounced diplopia. I referred him to Drs. Agnew and Webster, and did not see him again until the present entry. I suggested to him at the time the possibility of an incipient "trouble with the spinal cord," having tabes in my mind, but recovery from double vision seems to have satisfied him. Dr. Webster's report upon the condition of the eyes at this date is given later on. Further symptoms may be briefly mentioned as follows:

Ataxia; with inner surface of the feet approximated and eyes closed he falls at once, unless sustained. Gait tottering and swaying, quick "slinging" to one side or the other; front of thigh muscles in tonic contraction; "can't walk with eyes shut or in the dark unless has hold of something;" inco-ordination of legs with purposed movements extreme; no extension of disease to the arms.

Pain.—Severe lancinating pains in both legs began about one year ago. He then "had very severe sciatica;" was six weeks in bed, and was under treatment by Dr. Becker, of Morristown. After this attack the legs seemed to become unmanageable and "tired all the time." "Couldn't control them in getting into a wagon or going upstairs." Has had many attacks of "sciatica;" since and after each one the use of the legs became more impaired. The last and worst attack was in November, 1888, and he has scarcely left his house up to his present visit to me. Severe pain in lumbar region at times.

Other sensory disturbances.—"Girdle" sensation from knees down to ankles. Legs from below knees feel as if tightly bandaged, are numb and generally cold, especially the back part of the leg. "Feels as if walking on some strange object," and often removes his boots in order to adjust his socks. "Legs get very tired after walking a little."

Other symptoms.—Urination very slow. Immediately following November, 1888, had increased sexual desire—now practically impotent. About every other night has an involuntary seminal emission which wakes him up. Associated with this are dreams.

No gastralgic, nephralgic, or bronchial attacks. No especial vaso-motor disturbance, except feet always cold. Only trophic disturbance, a recent severe attack of herpes on the inner surface of the forearm. Knee-jerk abolished.

Any history of venereal disease denied, and no evidence of it discoverable.

Eyesight.—Sees with difficulty since attack in November, 1888. After having been under suspension-treatment over a month I referred him to Dr. Webster for a report upon his eyesight with a request for notes upon the previous examination. Dr. Webster very kindly furnished me this record.

"April 4, 1886.

"Dear Dr. Morton: The following is a copy of my notes:

"November 15, 1886.—Thomas H——, aged thirty-two. Says he 'can't see to drive at all.' He has been laid up with rheumatism. R. V. = $\frac{8}{200}$; $\frac{8}{10}$ with $-\frac{1}{14}$ L. V. = $\frac{8}{200}$; $\frac{8}{10}$ with $-\frac{1}{14}$. Ophthalmoscope shows atrophy of both optic nerves; atrophic excavation of disks and lessening of size of retinal arteries. Patient had 'malaria' five years ago. Ord. $-\frac{1}{15}$ for both eyes.

"November 22, 1886.—The glasses make his eyes ache

[1] Le Progrès Médical, January 16, 1889: De la suspension dans le traitement de l'ataxie locomotrice progressive, etc. Résumé de la leçon du 15 Janvier, 1889, par M. le Dr. Gilles de la Tourette, Chef de Clinique.

Le Progrès Médical, February 23, 1889. De la technique à suivre dans le traitement par la suspension, etc. Par M. le Dr. Gilles de la Tourette, Chef de Clinique, etc.

very much. V. = $\frac{2}{3}\frac{0}{0}$ with them. Ordered to change to $-\frac{1}{14}$ which give V. = $\frac{2}{4}\frac{0}{0}$ and are much easier to the eyes.

"January 22, 1887.—R. V. = $\frac{2}{4}\frac{0}{0}$; L. V. = $\frac{2}{1}\frac{0}{0}\frac{0}{0}$ with his glasses ($-\frac{1}{14}$).

"April 4, 1889.—R. V. = $\frac{2}{1}\frac{0}{0}\frac{0}{0}$; $\frac{2}{1}\frac{0}{5}$ with − 2.50 D. L. V. = $\frac{2}{1}\frac{0}{0}\frac{0}{0}$; $\frac{2}{1}\frac{0}{5}$ with − 2.50 D. V. = $\frac{2}{2}\frac{0}{0}$ with − 2.25 D, both eyes, $\frac{2}{1}\frac{0}{5}$ with both at once. Hyperphoria O°, esophoria 3°, with or without correction of refraction. Sursumduction, R. 3°, L. 3°; abduction, R. 6°, L. 9°; adduction, 18°.

"Ophthalmoscopic examination shows atrophy of both optic nerves, more marked in left eye. Retinal veins normal or slightly enlarged; retinal arteries diminished in size from one-third to one-half. Atrophic excavation of both optic disks. Pupils react slowly to light and to accommodation. The greater contraction of his visual and color fields in the left eye than the right corresponds to the more advanced atrophy of the left optic nerve. It is remarkable that he retains perfect central vision.

"Yours sincerely,
"D. WEBSTER."

Dr. Webster notes that the pupils react slowly to light; this was after about twenty suspensions. Before treatment there was absolutely no reaction to light. In another case, after about an equal number of suspensions, the pupils, from "pin-point" and no reaction, have returned to their normal size and react well.

Treatment.—Suspension.

March 6th.—Suspension now three minutes every other day. Had a severe cramp, like a "crick" in the back of the neck; lasted about a minute and soon wore off. The back strap of the apparatus against the neck probably pressed in upon the muscles, already in a state of abnormal irritability. It should bear squarely upon the occiput.

March 8th.—Suspension, five minutes. Walks better; stands better with closed eyes; legs less heavy and tired. Herpes on left arm severe. Again a cramp of brief duration.

March 15th.—Improvement in gait now very manifest. Has never since November last been so free from pain; "legs don't ache as they did when he goes to bed." Can now walk with a fairly free step and without any cane and without watching his feet; however, in doing this he still swings unexpectedly to one side or the other.

Patient was obliged to return to his home, and was furnished with an apparatus with instructions to suspend himself every other day.

April 4th.—Patient enters the office in striking contrast to his first visit. He carries a light cane, more from habit than from necessity, and walks with a long free gait. Allowance, of course, is to be made for the effort to do his best; but, as evidence of his improved walking, he mentions that friends walking behind him had not believed it could be he, so well was he walking. Has no pain in his back, and has had but one sciatic attack during his absence. This attack lasted four hours, whereas it ordinarily lasted two days. The pain was not severe. Improvement is equally well marked in standing with closed eyes. He can do so with but a moderate swaying of the body. The pupils now appear about normal and contract by light; knee-jerk continues to be absent; the slow urination has become free. The seminal emissions have ceased —he "wakes up just in time to stop it." Impotence has almost disappeared. There are no abnormal sensations about the legs and feet.

April 5th.—Yesterday patient felt his power to walk so much improved that he had walked without immediate fatigue fifty blocks, or two and one-half miles, and climbed the Elevated Railroad stairs several times; therefore today his gait is less free but still good; his legs felt tired. I was at first in doubt whether under these circumstances to suspend, but did so for five minutes, he himself drawing himself up until the tips of his toes just touched the floor. The immediate result of the suspension was remarkable. All sense of fatigue disappeared from the legs and he again walked with the freedom of the day before. Previous to treatment he could with great difficulty walk one block, and could not walk even across his room without the aid of two canes.

Summed up we have, in this case, attacks of shooting pains ceased; walking improved, from the restricted gait of the confirmed ataxic to a fairly free and long stride; swaying symptoms with closed eyes improved from a condition of precipitate fall to a sustainable though moderately swaying attitude; pupils exhibiting accommodation to light and more naturally dilated; sexual power fairly well restored; girdle sensation and other sensory disturbances about the legs and feet disappeared, and urination with natural flow in place of retardation.

I should add here that other cases now under treatment improve mainly in similar respects, some more, some less, but all showing a steady gain.

In a suspension-treatment begun March 2d, during a sharp attack of pain, the pains ceased immediately after the suspension, and the patient fell into a refreshing sleep.

In another case a profuse discharge from the great toe-joint has almost ceased.

In no case has any untoward result occurred, with the exception of the cramp in the neck alluded to, and in one case an increased hyperæsthesia of certain large areas of skin. In this latter connection may it be true that slight elongation of the spinal cord increases its irritability, while greater elongation diminishes it, just as in the trunks of individual nerves? From this point of view, differences in the results which may be recorded in forthcoming reports of cases may be explained.

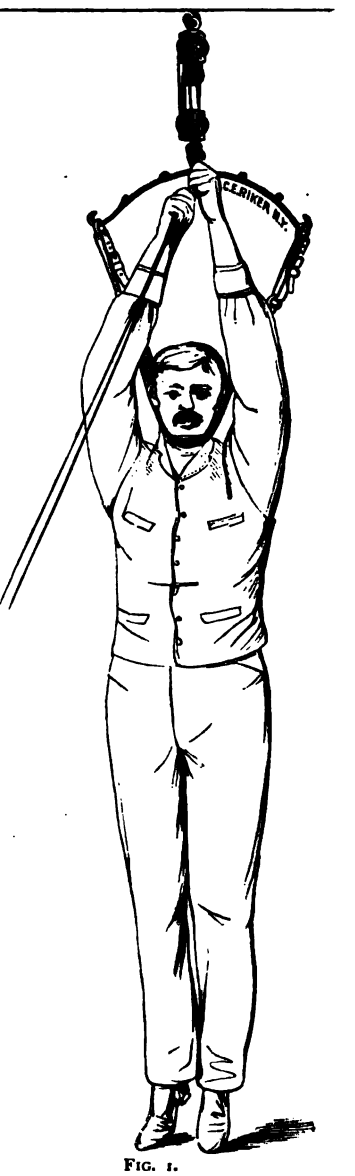


FIG. 1.

In respect to the influence of suspension upon impotence, the curative effect produced is only another of many curious illustrations of the fact that science often arrives at a rational treatment which has been previously popularly and empirically known. Years ago, in Paris, a brief "hanging" as a cure for this trouble was commonly spoken of as a treatment—extreme, to be sure, but frequently practised and often efficacious. In this same connection it may be borne in mind that the post-mortem inspection of criminals who have suffered death by hanging has revealed that a seminal emission had occurred. One further peculiarity of the suspension-treatment of the cord in tabes is the rapidity with which a change in symptoms is brought about. The effect is often immediate, and though of but few hours' duration may be again secured

at the next suspension, lasting apparently longer and longer, in direct ratio with the renewals of treatment.

The Sayre suspension-apparatus complete has a tripod and arm-straps. In place of the tripod a strong hook may be screwed into a beam in the ceiling. In regard to the arm-straps, I find in practice that they may be omitted in a large number of cases, with great advantage. For, so far as the suspension-treatment goes, patients having locomotor ataxia divide themselves into (1) those who can use their arms and suspend themselves, and (2) those who cannot use their arms to pull upon the ropes and must be suspended by another.

The former class may be treated, it seems to me, to the best advantage as shown in Fig. 1. The raised arms, straight or nearly so at the elbows, give a maximum distance between the distal extremities of the brachial and sacral plexuses, elongating the spinal cord for that reason and joining the effect thus produced to that brought about by the suspension of the body from the head. There is the further advantage that the patient feels more confidence in being allowed to gradually pull himself up. To secure the full advantage of this self-suspension I have invented a handle which, while sliding up the rope with freedom, will grip it on being pulled downward. Thus the patient gains each fraction of an inch that he can push his hands up and is relieved from the cutting of the rope, unbearable even to a sound person when protracted to five minutes.

Fig. 2.

This apparatus will be described in a subsequent issue of The Medical Record.

For the second class of patients, viz., those who must be suspended by another, and many of whom are practically so much dead weight so helpless have they become, the arm-straps are indispensable. Such a patient may be first placed in a chair and the arm straps adjusted so as to take a fair portion of the weight of the body, the head-strap adjusted to take a certain other portion of this weight, and, finally, when all is ready, while an attendant steadies the patient and raises him upright, the physician may bring about the desired suspension.

Figure No. 2 represents an instance of this class.

As to the duration of suspensions, I find it a simple matter to begin with from one to two minutes, and extend it to from five to seven minutes. Every other day seems to be often enough. The toes probably should not leave the floor in self-suspension, nor in suspension by the arm-straps, but I have patients of light weight who can swing themselves clear of the floor, and have myself unintentionally raised the helpless class, wearing arm-straps from the floor. The better plan, with patients of this latter class, would seem to be that suggested by Charcot, viz., to suspend them as much as practicable from both head and axillæ, the balls of the feet resting upon the floor, and to raise the arms frequently in order to hang additional weight upon the head.

Finally, what are the effects of suspension upon the healthy spinal cord; what the cause of the effect upon the diseased cord; is it due to a diminution of the irritability of the cord by stretching it and temporary, or, by reason of frequent and forced reduction of abnormal irritability, likely to become permanent; whether the cord can or can not be actually elongated; what results may be obtained in other diseases, and whether a restoration of function may not influence the condition of a lesion? All of these questions and many more of them, some of them speculative, some of them demonstrable, arise, but extend far beyond the scope of this present communication.

The subject is but just entering upon its experimental and clinical stage even in locomotor ataxia, but if we accept the facts thus far reported, and if they prove to be repeatable in a large number of cases, we shall be obliged to admit that the sum total of improvement and cure, be it temporary or permanent, is far in excess of that attainable by any previous means, and as such must be regarded as the most signal advance yet made in the treatment of this hitherto intractable disease.

Progress of Medical Science.

Jaundice Following a Stroke of Lightning.—Dr. C. Gerhardt has published an account of the case of a person who had been struck with lightning. The patient came under treatment a few hours after the accident, having regained consciousness, but having no remembrance of what had occurred. The course of the current was shown by burning of the hair, and by the characteristic arborescent figures, especially on the back. There was hæmatogenous jaundice, apparently due to the action of the electric current on the coloring matter of the blood, and the nerves and muscles were over-sensitive to both the faradic and the galvanic current.—*The New York Medical Journal.*

A Case of Exostosis Bursata.—As a rule, the reports of the removal of tumors by surgeons have lost their charm for the general reader, but cases of extreme infrequency always excite interest. Such a case is that reported by Dr. Bell (*Annals of Surgery*, February, 1889), which is, as far as he can learn, the third of its kind described in medical literature. His patient, a stout, healthy man of twenty years, entered the Montreal General Hospital in March, 1888, suffering from a tumor on the inner side of the lower end of the right femur. It appeared nine years before, being, when first noticed, as large as a marble, soft, and movable. Growing steadily without pain, it had become firmly attached to the bone five years after its appearance. Dr. Bell cut into the tumor, which was now as large as a base-ball, meeting first a synovial-like sac from which an ounce of liquid resembling synovial fluid escaped. In this fluid were floating fifty-five pieces of hyaline cartilage of the size of a pea or bean. Surrounded by the fluid, except where its bony pedicle, ¾ by ½ inch in diameter, united it to the linea aspera below the epiphyseal line, was an osseous mass as large as a Fameuse apple, having its irregular surface covered with a mosaic of small isolated pieces of cartilage. The sac, which became continuous with the periosteum at its attachment to the linea aspera was lined with a synovial membrane like that of the knee-joint. The osseous growth was cut off with a chain-saw, its base was chiselled

smooth, and the patient quickly recovered. The first case of this sort was reported by Billroth in 1863, and Rindfleisch, after carefully studying it, decided that the growth had originated as an ecchondrosis of the cartilage of the joint; this afterward pushing out a portion of the synovial membrane which became detached and formed a separate sac for it. The second case, seen at Bergmann's clinic in 1884, was studied by Fehleisen, who decided that such growths were the result of accidental separation from the border of the joint elements, in very early fœtal life, of a group of cells which lay a long time inactive, and afterward developed bone, cartilage, and synovial membrane. Volkmann, reasoning from the presence of simlilar bodies in exostosis bursata connected with pseudo-arthrosis of the femur, and in ganglia, thinks that the growths under discussion develop from existing epiphyseal cartilage or joint cartilage according as they are extra- or intra-articular. Dr. Bell is sure that in the two cases described by Billroth and Fehleisen, as well as in his own, the growth was quite distinct both from the joint and from the epiphyseal cartilage. His case throws light upon the formation of floating intra-articular cartilages, which may be considered as bodies, arising from cartilage cells existing in the tufts of the synovial membrane, and becoming subsequently detached from their bases.

Blennorrhœa in Women.—During a period of six years Horand has had under his care 5,090 women and 764 little girls suffering with blennorrhœa, and it is upon this large number of observations that he gives us the present study. He is a firm believer in the gonococcus as the cause of blennorrhœa, and teaches that where the gonococcus is not found there is no blennorrhœa. In the women the parts affected are, in order of frequency, the urethra, vagina, glands of Bartholin, uterus, and anus. In little girls the order is vagina, urethra, vulva, and anus. Urethral blennorrhœa in women causes little disturbance; it may give rise to slight itching or more frequent urination; cystitis is rare. It may continue a long time, months or years, and is apt to remain limited to the urethra. Inflammation of the vulva is rare in women, more frequent in girls. It is generally consequent upon mechanical irritation, want of care, direct contagion, attempts at rape, or accidental from contact with objects soiled with blennorrhagic pus. It may exist alone or associated with elytritis or urethritis. The epithelium of the vestibule seems to offer a good deal of resistance to infection. Elytritis is more frequent—rather more in girls than in women. Uterine blennorrhœa is very rare—it was found only six times in four hundred and eighty-three examinations. It is the result of transmission from the vagina. Bartholin's glands are affected only secondarily. Anal blennorrhœa is more frequent in women than in men. It is the result both of mediate and of immediate contagion. Gonorrhœal rheumatism is very rare in women, as is gonorrhœal ophthalmia. For the treatment of urethritis the best means is nitrate of silver, a grain and a half to the ounce. For elytritis in a child, irrigations with a warm boric acid solution of one per cent. strength should be used; in adults, the silver nitrate in stick applied directly every four or five days. The same treatment is also best for the disease when it affects the uterus, the anus, or the conjunctiva.—*The New York Medical Journal.*

Is There a "Concussion of the Spine?"—Dr. P. C. Knapp, of Boston, in a comprehensive paper on the nervous affections following injury (*The Boston Medical and Surgical Journal*), arrives at the following conclusions: 1. Concussion of the spine, in the strict sense of the term, although probable, is still a matter of doubt. 2. Muscular strain, spinal irritation, and peripheral neuritis are not uncommon complications. 3. Injury may give rise, not only to gross mechanical lesions of the central nervous system, with symptoms coming on soon after the accident, but also to typical chronic degenerative processes of insidious onset. 4. Injury may also give rise to various functional affections of the nervous system, including psychoses, hysteria, and neurasthenia. 5. Hemianæsthesia is not pathognomonic of hysteria, but is found in other conditions. 6. Psychical disturbances—anxiety, hypochondriasis, depression, emotional disturbance, and lack of power of application—may exist alone or in conjunction with other affections. 7. The neurasthenic state is often produced by injury, but true hysteria is rare. 8. Both the hysterical and the neurasthenic states may be superimposed upon organic disease, obscuring the diagnosis. 9. There is a fairly typical symptom-complex, with psychical disturbances, paræsthesia, anæsthesia, slow and feeble movements, exaggerated reflexes, etc., which is not uncommon, and is probably due to organic disease. 10. The prognosis of these conditions is grave. Improvement is not uncommon, but complete recovery is rare.

Internal Electrical Treatment of Gastric Dilatation.—The cases of dilatation of the stomach to which direct electrical treatment is appropriate, according to Dr. Baraduc, are those only which are functional and dependent chiefly on atony of the solar plexus. In these he finds direct faradization not difficult to manage. One terminal of terra cotta is laid on the epigastrium, and the other of copper, in the form of a short stem, is passed into the stomach in the tube of a stomach-pump, and not allowed to come into contact with the gastric walls, by being kept some two inches above the tip of the tube. Before introducing the tube some mineral water is given to fill the stomach; and after the electric action has been begun and gently increased, the contraction of the stomach is generally clearly felt by the patient, and the results made manifest by some slight reflux of the contained water up the tube of the stomach-pump. The machine should be kept at work for five or ten minutes, and the tube then withdrawn. The rest of the treatment should consist in rest for the stomach, with some external friction with camphorated oil, a spare nitrogenous diet, with a little milk only as fluid. The points of improvement which generally follow are these: 1. There is complete disappearance of the aching pain in the back and the epigastrium. 2. Manifest contraction of the stomach can be determined, so that its lower border rises some two inches or more, and lies above the umbilicus. This second result is best obtained when the coils are of thick wire, but that is more irritating when the stomach is very sensitive. The pain, on the other hand, is best quieted by the action of coils of thin wire. 3. With the reduction of pain and contraction the thirst diminishes, and the quantity of urine passed increases to the normal. This may result from the increased absorptive power of the alimentary tract, and possibly also from the electrical stimulation of the renal ganglia. External faradization (Erb) or external application of a frequently interrupted continuous current (Dujardin-Beaumetz, Bardet), are methods which are far less efficient in those cases in which dilatation has gone far.—*The Practitioner.*

Bacteriology of Snow.—While the bacteriology of ice and hailstones has been studied with considerable success by Drs. Fränkel, Bischoff, Mitchell Prudden, Pumpley, Hills, Stoben, A. V. Poehl, Bordone-Ufreduzzi, Bujwid, etc., that of snow has been up to the present almost wholly neglected. Even in Russia the subject has been touched only in a cursory way by Professor A. V. Poehl, of St. Petersburg, in the *Vratch.* In it he points out: 1, that snow always contains viable microbes liquefying gelatine; 2, that, when snow falls, the first portions invariably contain greater numbers of bacteria than the subsequent ones (for example, 8,324 per 1 cubic centimetre of snow-water, against 3,380 several hours later); 3, that, when snow lies on the ground, the superficial layers become richer in microbes (for example, 780 just after the fall, against 962 about three hours later). The fact is of interest from a sanitary point of view, as Dr. Poehl's researches furnish an additional proof that exposure of microbes to low temperatures does not destroy their vitality; at least, in certain species of micro-organisms. In

many countries, such as Russia or Sweden, snow forms, so to speak, a natural ground or soil during several months of the year, receiving excrementitious matter and every possible kind of refuse and filth. In spring, when the snow melts, it is imbibed by the soil, carrying with it all the polluting matters referred to. Hence an interesting question arises: Are such microbes as happen to be present in these matters in any way changed by their contact with snow, or not? This point can be determined only by further bacterioscopic researches. A contribution to the subject has just been published by Dr. F. G. Ianovsky, of Kiev, who has examined bacterioscopically, under Professor K. G. Tritshel's guidance, a February snow in its purest state, collected both immediately and from one to three days after its fall. This observer has found: 1. That even when collected during its fall, snow is invariably found to contain living bacteria in considerable numbers, varying from 34 to 463 per 1 cubic centimetre of snow-water. 2. That their number does not decrease from exposure of snow to low temperatures (—16° C.) for several days. 3. That the following three species of microbes are met with constantly in great numbers: *a*, a large diplococcus composed of ovoid cocci, endowed with energetic motion, and characterized by its rapidly liquefying jelly; the test-tube culture on the third day, forming greenish colonies along the track of the needle, assumes the shape of a funnel-like sac with a whitish flocculent deposit, while on the fifth the whole medium becomes liquefied, the precipitate sinking to the bottom; on agar, a pale grayish-white streak is formed at the site of inoculation, on potato a fairly thick white film; *b*, small-sized cocci, often arranged two and two, energetically mobile, and slowly growing on jelly without liquefying the medium, the growth proceeding solely along the track of the needle in the shape of a narrow stripe consisting of non-coalescing minute points of a yellow color, while on the surface the colony is seen as a grayish-white, circular, slightly prominent patch with somewhat fringed edges; on agar, the coccus forms a white streak with sinuous edges; on potato, a gray film with a brownish tint; *c*, very large cocci, liquefying jelly as late as three weeks after inoculation, and growing along the track of the needle in the form of a sharply-defined streak of a beautiful pink color, with a slightly elevated pink circular patch or "cap" on the surface; on agar the microbe forms a freely-spreading white film with a rosy tint; on potato, a thick, tallow-like, pink coat with sharply-defined fringed contours. 4. That the first two species (*a* and *b*) are also met with commonly in the water of the river Dnieper, which flows through the town, while the peculiar pink micrococcus seems to occur only in snow. 5. That, generally speaking, the microbes liquefying jelly in falling or recently fallen snow are met with invariably in far greater numbers than in snow which has been on the ground for some time; this, in fact, very often contains only such bacteria as do not liquefy gelatine. 6. That the bacteria of snow originate partly from aqueous vapors which are transformed into snow; partly and chiefly from the air, that is, they are carried away by the snow-flakes on their passage through the atmosphere.—*The British Medical Journal.*

THE MORTALITY OF PNEUMONIA.—Dr. Osler states that hospital statistics do not warrant the assertion that there has been any marked increase in the mortality from pneumonia of late years, as asserted by some, although the census returns of the United States favor the latter statement. But, as Dr. Billings points out, the comparison with preceding years is inaccurate, since the data were very imperfect and unreliable. At the Pennsylvania Hospital, with a total of 704 cases since 1845, the mortality has been 29.1 per cent., a rate sometimes much exceeded, as in 1875 to 1877, when it was 39.2 per cent., and sometimes quite as much lessened, as in 1845–47, when it was only 16 per cent. In the Boston City Hospital for thirteen years the mortality was also 29.1 per cent.

Dr. Osler shows that in private practice the rate is lower than in hospitals, and points out that the increase of pauper populations in large cities is doubtless responsible in some measure for this diversity. Dr. Hartshorne's statement that the "mortality of pneumonia to-day is, under similar circumstances, more than twice as great as it was forty years ago," is not thus borne out; and Dr. Osler shows that in many cases pneumonia is absolutely uninfluenced by treatment. Yet those cases which do call for treatment are precisely those in which our methods are most futile.

Post-mortem records show how seldom a simple pneumonia, apart from chronic disease of other organs, is a cause of death, but Dr. Osler thinks that it may be useful to divide the fatal cases into three groups: 1. Those in which the death has resulted from such complications as gangrene, meningitis, and ulcerative endocarditis—conditions at present beyond our art to remedy. 2. Cases in which death has resulted from mechanical causes—overdistention and paralysis of the right heart. 3. The large group in which death has been due to failure of the general powers under the influence of the high fever, or of the specific poison, or of both combined.—*University Medical Magazine.*

A SIMPLE METHOD OF SECURING THE LINGUAL ARTERY DURING THE OPERATION OF EXCISION OF THE TONGUE WITH THE SCISSORS.—At a late meeting of the Medical Society of London (*The British Medical Journal*, February 16, 1889), Mr. F. Bowreman Jessett read a paper describing his method of tying the lingual artery in excision of the tongue. He said that in some cases of excision of the tongue with scissors the hemorrhage was often very severe and even alarming. Moreover, in many of the cases that died after this operation, the fatal result was due to the fact that a quantity of blood found its way into the air-passages, and septic pneumonia followed. If this were so, it was obvious that it was all-important to prevent hemorrhage as much as possible during the operation. Again, in removing the tongue with scissors, if the artery was not seized directly it was divided it often retracted, and the bleeding point was with difficulty seen and secured. He had had opportunities of putting the method into practice, and had found it easy and effectual. The operation was only applicable when the disease was limited to the tongue itself, and when the floor of the mouth was free. The tongue being drawn well out of the mouth, the frænum and mucous membrane of the floor of the mouth around the half, or whole of the tongue if the entire organ was to be removed, was divided in the ordinary way with scissors slightly curved upon the flat. The tongue next being drawn well forward and upward, a few fibres of the genio-hyoglossus muscles were divided and torn through deeply with the finger. An ordinary aneurism needle, threaded with No. 4 Chinese silk, was thrust deeply down between the two genio-hyoglossus muscles, the point being directed downward and backward until it was opposite the second molar tooth; the point was then turned outward and brought out of the incision previously made through the mucous membrane, unthreaded and withdrawn. The ligature was next tied firmly and as deeply as possible. A pair of clamp forceps, curved and somewhat larger than those in ordinary use, were passed down and made to catch the tissues on the distal side of the ligature, to prevent the possibility of the ligature being snipped as the tongue was being removed. If it was desired to remove the whole tongue, the same manœuvre was carried out, and the artery on the other side secured. The surgeon then could snip out the organ at leisure, with practically no hemorrhage.

ACCORDING to M. Moulé, domestic fowls are frequently the subjects of tuberculosis, the disease often involving the abdominal organs. *Paté de foie gras* is sometimes almost a pure culture of tubercle bacilli.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 13, 1889.

THE PREVENTION OF PHTHISIS.

ALTHOUGH phthisis is no longer regarded as a malady with a necessarily fatal prognosis, its mortality remains a deplorably high one. It is quite consonant with modern ideas of prophylaxis and sanitation to search for practicable means of preventing the further spread of this destroyer of mankind, rather than to do battle only for the army of those already doomed.

This aspect of the subject was prominently brought forward at a recent meeting of the London Epidemiological Society, in a communication made by Dr. J. E. Squire. The author held that a review of the conditions on which phthisis depends shows that (*The Lancet*) some of the most essential come well within the scope of preventive medicine. The discovery of the bacillus tuberculosis allows us to place phthisis in close relation to the class of infectious diseases toward the control of which preventive medicine has already done so much; and experiments have abundantly proved that tubercular disease can be communicated from affected animals to the healthy. That consumption can be communicated from person to person has long been a matter of popular belief, and cases were referred to which seem to prove that such is actually the fact. The dependence of tuberculosis upon the infective bacillus has been shown by numerous experiments. Phthisis, then, depends primarily upon the reception into the body of an infective particle or micro-organism; but a lowered vitality of the tissues places them in a more favorable condition for the development of the bacillus, and thus constitutes in the individual a predisposition to the disease.

Dr. Squire further stated that the bacillus may enter the body: 1. By inoculation through a cut or scratch. 2. By means of the genito-urinary mucous membrane. 3. By the product of conception, and by direct hereditary transmission. 4. By the mucous membrane of the alimentary canal. 5. By the mucous membrane of the respiratory tract, and by the air-cells of the lungs. The possibility of infection through the alimentary tract assumes importance from the prevalence of tuberculosis in animals which are used as food, and from the experimental proof of the infectiousness of the milk of tuberculous cows. The present state of knowledge on the subject points very strongly to the necessity for careful inspection of cattle kept for dairy purposes, and for precautions in using the milk, and possibly also the flesh, of diseased animals.

It was also pointed out that since infection through the respiratory system is more potent, and probably more frequent, than by any other means, and as the risk of infection is intensified by close contact and by the crowding together of sick and healthy, the necessity for free ventilation is apparent, and becomes more so when the predisposing causes are considered. The latter were considered under these headings: 1. Hereditary predisposition. 2. Influence of air and sunlight. 3. Age and sex. 4. Effect of certain occupations. 5. Influence of locality and habitation, which includes the consideration of climate and temperature, altitude, nature of the soil, density of population, and the condition of dwelling-houses, both as regards their construction and the overcrowding of the inmates. 6. Influence of certain diseases, local and general.

In-door and sedentary occupations, as well as those in which much dust is inhaled, are known to influence largely the prevalence of phthisis. Much of this among the persons following such occupations is preventable. Here, again, the basis of all preventable measures is found in efficient ventilation. The home-workers—*i.e.*, among tailors—are more difficult to deal with than the factory hands; but public work-rooms, in which men could find convenience for their work, might lessen the evils of the present state of things.

With regard to climate, its influence on the causation of phthisis is probably infinitesimal as compared with the effect of density of population. Overcrowding is of two kinds: The aggregation of buildings on a confined area, with insufficient open space around and between houses, and the crowding together of persons within the houses.

The author thinks that laws should be enforced regulating the width of streets, the amount of open space around houses, the minimum height of rooms and size of windows; and efficient inspection of new houses should be carried out before they are allowed to be occupied. Tenement-houses might be licensed to hold a certain number of inmates, and be liable to inspection. As many diseases which produce a general debility thereby predispose to tuberculosis, general sanitary and hygienic measures framed for the control of these tend to diminish the amount of phthisis in a community, and seeing that insufficiency of food, of fresh air, and of exercise, continued anxiety and mental depression, and dissipation must be included among the predisposing causes, the philanthropist may assist the sanitarian in the fight against this widespread disease.

Finally, Dr. Squire believes that the fundamental principles which must form the basis of any successful attempts to diminish the prevalence of phthisis are (1) to provide a sufficiency of fresh air in and around dwellings and work-places, and (2) to endeavor to improve the resisting power of the individual by physical training during the period of growth and development, and by exercise and recreation alternating with the work of maturer age. As the effects of phthisis in the individual are not confined to a single generation, but are handed down by hereditary transmission from parent to child, any cause which tends to increase tubercular disease among the adult members of a population must be regarded as tending to produce a progressive deterioration of race. It is, therefore, to the interest of the community to allow no time to be lost in

commencing a systematic attack against the preventable causes of phthisis.

Dr. Squire states his conclusions rather broadly, and his recommendations are lacking in detailed directions for the prevention of the spread of phthisis as it now thrives. A painstaking disinfection of all suspected matters is certainly not to be overlooked, and will, in time, accomplish much good. Of course all measures of intelligent sanitation tend to diminish preventable diseases, and if phthisis is to be regarded in this light it cannot escape its share of suppression. *A priori*, there is apparently no reason why man should not eventually remain the victor in the great struggle between animal and plant life. But before the sanitary millennium arrives, many a poor victim will be put to rest, beaten in the battle of human protoplasm against microbic supremacy.

SKIN-GRAFTING ON CANCEROUS ULCERS.

NOT the least of the many evils attendant upon ulcerating malignant growths which are too extensive for removal by the knife is the foul-smelling discharge which sickens the patient and destroys his already failing appetite, thereby hastening the fatal termination. Despite the free use of astringents and antiseptics the discharge often continues, and even a thorough scraping and cauterization of the surface afford, in most cases, but partial relief.

In order to remedy this evil, Dr. Kraske, of Freiburg, has had recourse to skin-transplantation and skin-grafting with, in several instances, notable success. He reports in the *Münchener medicinische Wochenschrift* for January 1, 1889, a case of epithelioma of the ear, which had involved the skin above, below, and behind the concha, and had perforated the skull in one place. After thoroughly scraping the surface of the ulcer he brought over a flap of skin from the back of the head, covering with it the greater portion of the cancerous surface. The flap united by first intention, and the remaining uncovered part healed by granulation. Another case was one of carcinoma of the breast, in which the neighboring skin was involved to such an extent as to render an operation useless. For the same reason it was impossible to secure a flap of healthy integument with which to cover the ulcerated surface. So, after cutting away as much as possible of the cancerous tissue, by means of a knife curved on the flat, he covered over the freshened surface with numerous skin-grafts taken from the arm of the patient. These pieces all adhered, and soon the ulcer had entirely healed, the "cancer apertus" being thereby converted into the much more endurable "cancer occultus," and the patient having obtained a short period, at least, of relief from her most troublesome symptoms.

THE MYCOLOGY OF THE FEMALE ORGANS OF GENERATION IN HEALTH.

A SYSTEMATIC investigation has been recently conducted by Dr. G. Winter (*Zeitschrift für Geburtshülfe und Gynäkologie*) in order to determine the nature of the microorganisms that are normally found in the sexual organs of healthy women. The author states that the Fallopian tubes in health contain no microbes of any kind, and this also applies to the cavity of the uterus. In about one-half of the cases examined, the region of the internal os showed the presence of various microbes. The cervical canal is almost invariably the seat of numerous organisms, and it is a noteworthy fact that their number rapidly increases in the condition of pregnancy. In the vagina in healthy women various microbes are a constant occurrence.

Dr. Winter has also found that there is a decided preponderance of staphylococci over other varieties of germs in the genital organs of women. He assumes that they are identical with the pathogenous cocci, but admits that his inoculation experiments were not conclusive. The explanation given of this apparent inconsistency is plausible enough; normally these microbes vegetate in a condition of lessened virulence. But if putrescible material or necrotic tissues supplant the healthy structures their original virulence is fanned into activity. The practical inference is seen at a glance; and it may be stated that most gynecologists are already practising the strict antisepsis which these observations would place in the light of an absolute necessity rather than an optional procedure.

STRYCHNINE AS AN ANTIDOTE IN NARCOTIC POISONING.

THE cause of death in poisoning due to narcotic drugs is quite generally supposed to be a paralysis of the respiratory centre. Dr. Gibson, writing in *The Practitioner*, says that "it appears difficult to account for the fact that strychnine, the most powerful stimulant to that centre which we possess, should not be recommended as part of the routine treatment for all narcotic poisons. Atropine at present is allowed to hold this position, but there is a stage in opium-poisoning at which the use of this drug is fraught with danger, and a patient may pass away in a condition of profound narcosis in which the action of atropine preponderates over that of the original poison."

In the cases of narcotic poisoning which have come under his own personal notice during the last three years, strychnine has been used hypodermically when there has been any irregularity or interruption of the breathing which appeared to threaten a failure of the respiratory centre. The effect of the drug was immediately shown by the increased rate, more regular rhythm, and greater depth of the respirations. And even in cases where breathing had ceased, it again commenced after the administration of strychnine.

After some general advice regarding the treatment of narcotic poisoning the author continues:

"Keeping the patient in the horizontal position, the respiration is to be carefully watched, and if there should be the least sign of irregularity, or shallowness, or inequality in the breathing, one-hundredth or one-fiftieth of a grain, according to the age of the patient, of sulphate of strychnine should be administered subcutaneously, and may be repeated, at intervals of an hour, two or three times. If, in spite of the strychnine the respiration becomes very feeble or ceases entirely, artificial respiration must be commenced promptly. The most convenient method to employ is that of Sylvester; and it should be persisted in until, on the one hand, the respiration is carried on by natural means, or, on the other, the heart has for half an hour ceased to beat."

Finally, Dr. Gibson points out that although narcotic poisoning appears to constitute the special field of use-

fulness for strychnine, impending death from respiratory failure in general anæsthesia may likewise be at times promptly averted by the subcutaneous employment of this drug.

News of the Week.

THE CONGRESS OF THE GERMAN AND VIENNESE ANTHROPOLOGICAL SOCIETIES will be held in Vienna from August 5th to 10th. A pre-historic exhibition will at the same time be opened in the Vienna Museum of Natural History.

STATE MEDICAL SOCIETY OF TENNESSEE.—This Society will meet in annual session at Nashville, April 30th, and continue in session three days.

PENNSYLVANIA STATE MEDICAL SOCIETY.—The fortieth annual meeting of the Medical Society of the State of Pennsylvania will be held in Pittsburg on Tuesday, Wednesday, Thursday, and Friday, June 4, 5, 6, and 7, 1889, commencing on Tuesday, June 4th, at 9 A.M.

NATIONAL ASSOCIATION OF RAILWAY SURGEONS.—The annual meeting of the National Association of Railway Surgeons will be held at St. Louis, Mo., on Thursday and Friday, May 2 and 3, 1889. Dr. W. B. Outten, of St. Louis, is the Chairman of the Committee of Arrangements.

THE CAUCASIAN MEDICAL SOCIETY of Tiflis celebrated the twenty-fifth anniversary of its foundation on April 12th. The record of the Society during the quarter of a century of its existence has been a good one, many valuable contributions to medical literature having first been presented at its meetings. Dr. A. Grigoryeff is the present secretary of the Society.

THE HEALTH DEPARTMENT AND THE QUESTION OF CONTAGIOUSNESS OF TUBERCULOSIS.—Resolved, that Drs. T. M. Prudden, H. M. Biggs, and H. P. Loomis, the pathologists of this Department, be, and are hereby requested to formulate a brief and comprehensive statement regarding the contagiousness of tuberculosis in man, stating therein the evidence of the same, and recommending in the briefest possible manner practicable, the simplest means of protection from its influence.

SECOND INTERNATIONAL CLIMATOLOGICAL CONGRESS.—From the French Ministry of Commerce and Industry invitations are being issued to assist at the second session of the Hydrological and Climatological International Congress. The first session, or congress, met at Biarritz in October, 1886, and at the time we published a short notice of the proceedings. The second session will be of more importance. It will be held at the Paris Universal Exhibition, and under direct Government patronage. The sittings will last from the 3d to the 10th of October next, and the delegates will have free admission to the Exhibition when the congress meets in the building. All members are charged a fee of twenty francs to defray the cost of publishing a full report of the proceedings. There will be three sections: (1) hydropathic section, (2) scientific and medical section, and (3) climatological section. Each has seven subjects for discussion, and printed papers will be issued previously to the meeting of the congress, so as to form a basis of discussion. The committee organizing the congress has selected M. E. Renou, director of the St. Maur Meteorological Observatory and vice-president of the Meteorological Society of France, as its president. Dr. Danjoy, president of the Medical Hydrological Society of Paris, is vice-president of the committee. Dr. F. de Rauce is secretary-general, and will supply all information to correspondents addressing him at 53 Avenue Montaigne, Paris.

DR. PRINCE A. MORROW, of this city, who has spent several weeks in Mexico and the Sandwich Islands in making personal observations of leprosy, to serve as the basis of a report before the Paris International Congress of Dermatology and Syphilography, which meets in August, has returned to resume his practice.

THE UNIVERSITY MEDICAL COLLEGE OF KANSAS CITY is the name of a newly organized medical college.

MEDICAL COLLEGE COMMENCEMENTS.—Degrees have been conferred as follows: Rush Medical College, 137; Chicago College of Physicians and Surgeons, 50; Jefferson Medical College, 212; Missouri Medical College, 82; St. Louis College of Physicians and Surgeons, 54; Western Reserve, Cleveland, O., 43; Pittsburg, Pa., 36; Atlanta Medical College, 43; Southern Medical College, 35; Indiana Medical College, 27; Toledo Medical College, 8; Albany Medical College, 20.

THE BILL TO ESTABLISH A STATE BOARD OF HEALTH IN FLORIDA has become a law.

AN INTERNATIONAL CONGRESS OF THERAPEUTICS AND MATERIA MEDICA.—In connection with the Paris Exposition of 1889, an International Congress of Therapeutics and Materia Medica will sit at the Hôtel des Sociétés Savantes, No. 28 Rue Serpente, from August 1st to 5th. All physicians, pharmacists, and veterinarians who register and pay the fee of ten francs will be considered as members. The Committee of Organization is composed of MM. Moutard-Martin, Dujardin-Beaumetz, Constantin Paul, P. G. Bardet, Labbé, and R. Blondel. Communications should be sent to Dr. Bardet, adjunct secretary-general of the Committee, No. 119 *bis* Rue Notre-Dame-des-Champs, Paris. Titles of papers to be read should be communicated to Dr. Bardet before May 15th. Each subscriber will be entitled to a copy of the volume of "Transactions."

DR. E. L. KEYES has resigned the chair of Genito-urinary and Skin Diseases at Bellevue Medical College, and is succeeded by Dr. Samuel Alexander, of the class of 1882.

DR. EDWARD PAYSON POND, of this city, who a week ago was appointed a vaccinator, died on April 3d, of malarial fever and complications. Dr. Pond had served several terms as vaccinator and summer corps inspector in the service of the Health Department, and was highly esteemed.

DR. VON LAUER died in Berlin April 9th. He was the physician of the late Emperor William of Germany.

MICHAEL EUGENE CHEVREUL, the well-known chemist, whose hundredth birthday was celebrated last year in Paris, died on April 9th. He was born in 1788, and enjoyed excellent bodily and mental health up to a short time before his death.

DEATH OF DR. J. H. KIDDER.—Washington sustains a severe loss, both scientifically and socially, in the death of Dr. J. H. Kidder, which took place unexpectedly on April 8th. Dr. Kidder was aged fifty years. He had been until six years ago a naval Surgeon, but had done much excellent work in natural history, and had been connected with the United States Fish Commission and the Smithsonian Institution. At the time of his death he was Director of the International Exchanges at the Smithsonian Institution.

DEATH OF DR. DUANE B. SIMMONS.—Word has come of the death, at Tokio, Japan, on February 19th, of Dr. Duane B. Simmons, a resident of Japan, with brief intermissions, since the opening of that country to foreign intercourse. He was born at Milan, Dutchess County, N. Y., August 13, 1832. He went out to Japan as medical missionary with the first mission sent out by the Dutch Reformed Church, in May, 1859. After a few months' service he made a friendly separation from the mission and devoted himself to the general practice of his profession among the foreign and native population of Yokohama. He returned to the United States in 1865, and after two years spent in study here and in Europe, went back to Japan. Soon after came the Restoration of 1868, and he became government medical director and instructor, and organized the first hospital service.

MR. JOHN BRIGHT'S MEDICAL AND SANITARY VIEWS.—The *British Medical Journal* says of the late Mr. Bright: "It must be confessed, however, that his attachment to the most extreme doctrines concerning the freedom of trade sometimes blinded him to the necessity of imposing restrictions in the interests of the health of the work-people, or of the public health. He was, in fact, more often an antagonist of sanitary legislation than one of its promoters; he did not approve of giving protection to the medical profession in its official relations, and he especially objected to the compulsory clauses of the Vaccination Acts. He was also an opponent of some of the provisions of the various Factory Acts and Labor Regulation Bills. That antagonism was due to an honest endeavor to prevent injustice to the manufacturer as well as hardship to the factory hands. His ideas upon such subjects were governed by his attachment to the principles of free trade."

PHILADELPHIA POLYCLINIC.—There has been great activity of late in the Philadelphia Polyclinic. New Chairs of Diseases of the Mind and Nervous System, and of Obstetrics and Diseases of Children, have been established, Drs. S. Weir Mitchell and Edward P. Davis having been elected to the respective professorships. Dr. Mitchell's service at the Infirmary for Nervous Diseases and Dr. Davis' Maternity Wards at the Philadelphia Hospital are thus added to the other clinical and hospital facilities. Dr. B. Alex Randall has been elected Professor of Diseases of the Ear, in place of Dr. Burnett, resigned. Professor Randall has the Ophthalmic and Aural Clinics of the Children's and Episcopal Hospitals. The hospital accommodations of the present building being insufficient, a very large lot about four blocks from the present location has been purchased, and work on a new building is being pushed. The State Legislature has recommended a grant of $20,000 from the Charities' Fund to aid in the erection of the new hospital, and subscriptions from individuals to the same amount are being solicited, about one-half of which has been secured. Several new departments of instruction have been added under charge of professors of existing chairs; notably the Department of Massage (Professors Mills and Wilson), the Special Ophthalmological Course (Professors Harlan and Jackson), and the Diet Kitchen (Professor S. Solis-Cohen).

DR. EDWARD T. BRUEN, Assistant Professor of Physical Diagnosis in the University of Pennsylvania, died of pneumonia last Sunday, after a brief illness. He was born in 1851, and graduated in medicine at the University of Pennsylvania in 1873. He was visiting physician to the Philadelphia and German Hospitals, and the author of a favorably known work on the "Physical Diagnosis of the Heart and Lungs," as well as of numerous contributions to our periodical literature. He was an earnest student, a close clinical observer, and a skilful practitioner, and his death is a loss to his profession and to the community in which he lived.

CONVENTION FOR REVISING THE PHARMACOPŒIA.—Dr. Robert Amory, President of the Convention of 1880, calls upon the several incorporated medical societies, incorporated medical colleges, incorporated colleges of pharmacy, and incorporated pharmaceutical societies throughout the United States of America, the American Medical Association, and the American Pharmaceutical Association, to elect a number of delegates, not exceeding *three*, and upon the Surgeon-General of the Army, Surgeon-General of the Navy, and the Surgeon-General of the Marine Hospital Service to appoint, each, not exceeding *three* medical officers, to attend a General Convention for the Revision and Publication of the Pharmacopœia, to assemble in Washington, on Wednesday, May 7, 1890, at noon. The several bodies, as well as the Medical Departments of the Army, Navy, and Marine Hospital Service, are requested to submit the Pharmacopœia to a careful revision, and to transmit the result of their labors to the Committee of Revision at least three months before the meeting of the General Convention. The several medical and pharmaceutical bodies are requested to transmit to the President of the Convention of 1880, the names and residences of their respective delegates, as soon as they shall have been appointed; a list of these delegates will be published, for the information of the medical public, in the newspapers and medical journals in the month of March, 1890. If any body other than those admitted in 1880 shall desire a representation in the Convention of 1890, it is suggested that the proof of incorporation, signed by the Secretary of State of the State which shall have issued the charter, or by properly qualified public officials of the United States, be presented with the credentials of the delegation. A blank form of certificate of appointment of delegates will be sent upon application by letter to Dr. Robert Amory, care of Dr. Edwin H. Brigham, 19 Boylston Place, Boston, Mass.

A CHAIR OF BALNEOLOGY.—The University of Vienna has admitted balneology as one of the recognized subjects of instruction, and has made Dr. Clar, of Graz, a privatedocent in balneology.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, March 1, 1889.

FRANCIS P. KINNICUTT, M.D., PRESIDENT, IN THE CHAIR.

THE PRESIDENT presented a male patient, aged forty, suffering from

SPLENIC LEUCÆMIA.

There was a very imperfect history of exposure to malarial influences. The patient had enjoyed good health until April, 1888, when he began to suffer from the usual symptoms of anæmia. In June of the same year he noticed that his abdomen was slightly swollen. From this date the swelling had gradually increased, and he had suffered from progressive discomfort, weakness, breathlessness, palpitation, and from fatigue on slight exertion.

On admission to St. Luke's Hospital he complained of the above symptoms, and on examination the spleen was found to be enormously enlarged, occupying the whole of the left hypochondrium, crossing the median line at the level of the umbilicus, filling the pelvic cavity, its lower border being felt just above the symphysis and easily palpated by the finger in the rectum. The shape of the normal spleen was perfectly preserved, the enlargement being very symmetrical; the usual indentations of the anterior border were well marked. The liver was also greatly enlarged, its lower border reaching a point below a line drawn through the umbilicus. There was no enlargement of any of the superficial glands; the tonsils and pharynx were free from leucæmic disease. The detection of any enlarged mesenteric glands was rendered impossible through the presence of the splenic and hepatic tumors. There was marked sensitiveness over the lower third of the sternum, but no apparent swelling or softening.

An examination of the blood showed the presence of 2,987,500 red blood-disks per cubic millimetre, and a ratio of white to red cells of one to a little less than four. The hæmoglobin percentage was forty-five. The red disks presented no striking changes, with the exception of a few well-marked nucleated red corpuscles, such as occur in the fœtus and in the red marrow of the adult. There were occasional microcytes and megalocytes. The colorless corpuscles presented various forms, viz.: (*a*) Cells of normal size with several nuclei and granular protoplasm; (*b*) large polynucleated cells, resembling marrow-cells; (*c*) very large mononucleated forms. Erlich's method of staining showed a great number of leucocytes reacting with eiorsin. In normal blood very few occur.

Charcot's crystals were not observed.

During the period the patient had been under observation there had been no elevation of temperature. During the entire course of the disease there had been an absence of hemorrhages. The urine contained albumin and hyaline and granular casts. The tenderness over the sternum, in the absence of swelling or softening, could not be considered as a positive indication of any change in the bone-marrow. The patient had come to New York in the hope that the removal of the spleen might be thought feasible. The speaker believed, however, that surgical interference was positively contraindicated.

DR. GEORGE L. PEABODY then read the paper of the evening (see p. 399) entitled

CHRONIC INTERMITTENT FEVER OF NON-MALARIAL ORIGIN.

DR. A. B. BALL said that the patient referred to by Dr. Peabody had been under his care for three months last year, and he had been completely nonplussed to account for the high temperature. The appearance of the girl during the attacks was certainly very extraordinary. While she was under his observation the attacks recurred with considerable regularity, but now this feature of the case had disappeared. These cases of intermittent fever, which were not malarial and could not be traced to any of the more common causes of such a condition, were very puzzling.

DR. BEVERLEY ROBINSON said that there was a patient now in St. Luke's Hospital who seemed to him to be an example of the kind referred to in Dr. Peabody's paper, at least so far as the condition of chronic intermittent fever, non-malarial in its origin, was concerned. The patient, a lad thirteen years of age, had been seen by several members of the Society present. When he came into the speaker's service, in December, 1888, he gave a history of an acute attack, which at first simulated both malarial and typhoid fever. Subsequently, however, it was thought that he had a forming perityphlitic abscess. Later still he was operated on under the supposition that he had pus somewhere in the abdominal cavity, and presumably in the liver. Despite every possible investigation the nature of this boy's ailment was undiscovered. He had, during two months, each successive day in the afternoon, a marked chill, accompanied and followed by a high elevation of temperature. Each morning the patient was again apyretic, although gradually growing weaker and more prostrate. In this instance active medication directed against any possible malarial origin of the disease remained without the slightest appreciable good affect. Finally it was abandoned and operative interference was sought, with, as had been said, an equally negative result. At present, after three months' duration of disease, during the greater portion of which time the lad's condition inspired the greatest anxiety, he seemed to be convalescent, and was in a fair way to recover entirely. What was the occasion, however, of his successive chills and high temperatures remained as much a mystery as before.

DR. GIBNEY referred to a case reported in *The Lancet* in which the temperature rose to an extraordinary height. The case was thought to be hysterical in its nature.

DR. W. M. POLK said that the case was very similar to one he had seen in St. Luke's Hospital about ten years ago. The same patient subsequently came to Bellevue Hospital. This patient's temperature was taken in the axilla, mouth, anus, and vagina, and she was watched very carefully to make sure that no deception was practised. The mercury repeatedly ran up to 110° and 115° F., the highest points that the two thermometers used could register. The temperature was not constantly so high, but varied considerably within short periods of time. The patient was markedly hysterical. He had seen another case of very high temperature. The patient died, but at the autopsy nothing could be found to account for the hyperthermia. Cases of this sort, the speaker said, are certainly very perplexing, and we are unable as yet to explain them.

DR. KINNICUTT said that he could not but suspect that Dr. Peabody's case might prove to be one of pseudo-leucæmia.

Certainly the existence of this disease for so long a period without evidence of involvement of the superficial glands must be very rare; yet Ebstein's case, quoted by Dr. Peabody, was an example in point. Again, the glandular mass found in the abdominal cavity when exploratory laparotomy was performed might be regarded as suspicious. The maintenance of a fair nutrition by the patient did not necessarily militate against the existence of a pseudo-leucæmia. In pernicious anæmia a large amount of adipose tissue, particularly in the abdominal walls, was frequently retained to the last.

DR. A. A. SMITH said that he was once called in great haste to see a patient, and found the temperature 110° F. The temperature was taken several times, but was always the same. He was unable at first to account for it, but further investigation revealed the presence in the bed of

a hot water bag. He asked whether an elevation of temperature was an accompaniment of true hysteria.

Dr. Beverley Robinson presented

AN IMPROVED NASAL INHALER,

the object of which was to facilitate the use of dry vapors in the nasal passages (see p.390). Any volatile liquid substance, such as eucalyptol, creasote, pine-needle oil, etc., might be used with this inhaler. The speaker preferred pine-needle oil because of its efficacy and agreeable odor. The inhaler had been of service in relieving moderate degrees of obstructive disease of the nasal fossæ, due to vascular turgescence, or even to hyperplasia, of the pituitary membrane covering the turbinated bodies and septum.

Dr. Robinson then made a few remarks in regard to

THE USE OF DRY VAPORS IN THE NOSE.

It had been his conviction for many years that douches of any kind were injurious when employed in the treatment of hypertrophic rhinitis, and he believed the same was true, in a less degree, of all the forms of sprays in ordinary use. He had, however, had most satisfactory evidences of the utility of dry vapors, judiciously inhaled at proper intervals and during a sufficient length of time. He had found them efficacious in subduing irritation and in promoting the resorption of tissue, provided the disease were neither too pronounced nor of too long standing. In any case they could do no harm, and they often obviated the necessity of a painful operative procedure. He had never found that the use of these dry vapors aggravated a previous uncomfortable condition, as that of cocaine and other substances employed as sprays not infrequently did. The vapors could be employed by any practitioner, no matter how great or how little was his acquaintance with rhinology. He believed also that the otologists would find such a principle of medication of great advantage in the treatment of various forms of middle-ear disease.

The President reported two cases of

LEAD-POISONING

occurring from an unusual source. The first patient was admitted to St. Luke's Hospital suffering from lead colic and "wrist-drop." He had been employed as a florist, and on investigation by Dr. Vaughan, the house-physician, it was found he had been in the habit of biting off the ends of the tin-foil used as wrappers for hand-bouquets. The tin-foil used for this purpose contained as much as eighty per cent. of lead. There was no history of other sources of lead-poisoning. The second patient was admitted to the hospital suffering from lead colic, and presenting a typical blue gum-line. He had been in the habit, for several weeks, of drinking beer from bottles which, he said, were cleaned by his employer with lead shot.

Dr. R. F. Weir recalled the fact that several cases of lead-poisoning, some years ago, had been traced to the use of a popular brand of chewing tobacco which was wrapped in tin-foil.

Dr. Dana referred to some cases of poisoning which had been traced to the consumption of certain beverages coming in bottles with so-called patent stoppers. He said that he had recently had two Chinese patients in his hospital service, both of whom were suffering from lead-poisoning. He was unable to trace the source of the poisoning.

Dr. Peabody related a case of severe epistaxis for which acetate of lead had been ordered. The remedy produced the desired effect in arresting the hemorrhage, and the patient continued to take it in daily doses of twenty grains for five days. The result was a typical and well-marked case of lead-poisoning.

Dr. A. A. Smith reported a case of lead-poisoning following the use of diluted (1–4) Goulard's solution. The application was discontinued, and in a short time the symptoms of plumbism disappeared.

The Society then adjourned.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON LARYNGOLOGY AND RHINOLOGY.

Stated Meeting, February 26, 1889.

Clarence C. Rice, M.D., Chairman.

Dr. Wales L. Cary presented

A CASE OF EPITHELIOMA OF THE SOFT PALATE,

with the following history: On February 18th Ferdinand H——, sixty years of age, an Austrian, and by occupation a shoemaker, presented himself for advice concerning a growth of the velum palati, which gave him distress on swallowing. He stated that about one year ago he had an attack of acute inflammation of the fauces, which his attending physician called "a touch of diphtheria;" yet on his own evidence there was no fever and he received no special medication. Soon after this his son noticed a prominent white spot, like a "small split bean," just at the junction of the uvula and the palatine arch. In this there was no pain or tenderness, and no distress or embarrassment on swallowing. In three months it had attained the diameter of five-eighths of an inch, was regular in outline, and still produced no subjective symptoms.

At this stage it was seen by a physician, who removed it with an apparatus which from the patient's account must have been the electro-cautery. During six months he gave it no attention, nor did it cause him any distress; but now, and for three months past, it has occasioned increasing pain on deglutition. Although he has lost much flesh he is still fairly well nourished and strong; no cachectic look has appeared; he denies syphilis, and there are no objective signs of that disease. None of his family have had a similar affliction, and his nine children are all living and healthy. He is not at all intemperate, but up to the beginning of this trouble was an inveterate smoker.

Ten days ago the growth presented a regular outline, very slightly indented, where indistinct lines, slightly contracting, converged toward the centre, the whole mass being elevated above the surrounding tissue perhaps one-tenth of an inch, yet its surface followed the normal conformation of the roof of the mouth. It is semicircular, one inch in diameter, and is convex anteriorly.

At this stage Dr. Rice removed and submitted a small piece to Dr. J. H. Linsley for microscopical examination, who reported as follows: "The tissue examined by me is found to contain epithelium of the squamous variety, and the tumor is undoubtedly epithelioma."

Now the condition will be found materially changed; the elevated distinct outline is merged into the general swelling of the whole of the soft palate. One small spot appears about to break down, being of a yellowish color, and slightly irregular outline. Pain and difficulty in swallowing have increased; there is no interference with the proper palatine function in closing the naso-pharynx, and as yet there is no glandular enlargement.

Dr. Cary then demonstrated the condition found in the patient, and also the use of

A NEW ORAL SPECULUM.

This speculum is made in four different sizes, and consists of variously shaped cylinders so arranged that the struggling of the patient will tend to open the speculum and make the view more distinct.

DISCUSSION ON DR. GERSTER'S PAPER.

Dr. Dillon Brown opened the discussion (*vide* p. 365) on Dr. Gerster's paper by stating that he had been requested by the Chairman to make a few remarks upon the value of intubation in the treatment of tumors of the larynx. In view of the fact that he had operated upon the reader's second case to enable him to dispense with the tracheotomy tube, he thought that it would be more interesting to complete the history of that patient. This man continued to

wear the cannula in the trachea until March 25, 1887, when Dr. Brown performed intubation, with the assistance of Dr. W. H. Wilmer and Dr. Howard Lilienthal. There were also present Dr. H. E. Sanderson, Dr. H. S. Stark, Dr. G. C. Rich, Dr. E. F. Walsh, and Dr. C. E. Giddings, members of the house staff of Mount Sinai Hospital. Two previous attempts had been made without ether and failed, owing to the lower end of the tube engaging in the external opening. He was of a very nervous, irritable temperament, and the tube gave rise at first to excessive irritation, which called for the frequent use of opiates. The irritation was not so great after the first day or two, but it is safe to say that toleration was never fully established in this case. The tube was removed in a week, and there was no return of the dyspnœa. By his presence here to-night it can be seen that intubation has permanently relieved the patient of his tracheal cannula.

In gumma and other forms of syphilitic stenosis, we find the most brilliant field for this method. Without a formidable operation, the dyspnœa is immediately and completely relieved; and, besides the curative effect obtained by the constant pressure of the tube, time is gained for the action of internal medication.

Dr. Brown said that until recently both Dr. O'Dwyer and himself had believed a permanent cure could not be obtained by dilatation in cicatricial stenosis of the larynx; so it was their custom to introduce the tube for twenty-four hours and give the patient freedom from the trouble for a month or two, and then repeat the process. More recently they had become convinced that by constant dilatation, the tube remaining in the larynx permanently, the tendency to contraction of this cicatricial tissue could be permanently overcome. He had under observation at present two cases—one having gone six months, and the other over a year, without interference—both of whom had laryngeal stenosis due to syphilis.

After the members had examined the patient, Dr. Arpad G. Gerster said that although the glands were not yet involved he would not recommend an operation at all in the case, as the disease was so extensive that a complete removal would not be practicable.

Dr. D. H. Goodwillie said he had a case at present having a similar lesion; there were no glandular swellings at present, but the base of the tongue was already considerably indurated. He did not consider any operative procedure called for at present.

The Chairman spoke of the changes in the growth since he last saw the patient. The growth was a perfect circle at first, with an unbroken surface, soft and pulpy to the touch, bleeding very easily when gently touched with a probe, and seeming to be entirely limited to the soft palate, and not involving the pillars of the pharynx at all. Since then it had changed much in color, and had become an ulcerated surface and had involved the pillars of the pharynx.

Dr. J. M. W. Kitchen presented a nasal plug that he had used for several years with much satisfaction. The principal feature of it was a tin core which could be cut out of thin sheet metal at the time it was needed. This core is wound with cotton which can be impregnated with antiseptics or other substances as desired, and then anointed with vaseline and inserted into the nose with dressing forceps. It enables one to apply pressure exactly where it is needed, and the plug will retain its position. He claimed that when the plug was made antiseptic and kept properly cleansed after introduction it would remain for three or four days, in cold weather, without becoming offensive. The following are some of its chief uses:

1. To prevent adhesion of opposing surfaces.
2. To gain increased space by dilatation, not only after operations but in other instances.
3. To prevent the clogging up of the nose by dried secretions.
4. To secure good intranasal alignment.
5. To repress exuberant granulations, and maintain in apposition flaps of mucous membrane after operations.
6. To make topical applications when required.
7. Occasionally to check hemorrhage, although usually tampons are preferable.
8. To afford protection to and make pressure on ulcers in healing.

Dr. Goodwillie said that where it was necessary to prevent the union of opposing surfaces he found the instrument worked well. He had used celluloid in much the same way as the tin, and liked it rather better. In prolonged treatment, a soft rubber intarnasal tube which will allow air to pass through is more efficient and is a great comfort to the patient.

Dr. Gerster presented two patients who had been operated on for laryngeal growths, together with the specimens removed.

Case I.—The specimen represents the tumor itself removed from the larynx of this patient. On one side it is covered with normal mucous membrane, although shrunken a good deal in the alcohol; on the other side it is ulcerated.

Case II.—The second specimen also represents a tumor of the larynx with a foreign body embedded in it. The foreign body caught in the pharynx or upper part of the œsophagus, and probably perforated into the larynx. It was found embedded in a mass consisting of four or five dense granular bodies. A diffuse perichondritis also existed, causing intense dyspnœa and dysphagia. Tracheotomy and laryngotomy were resorted to, and in extirpating the tumors this foreign body was removed unexpectedly. It is very likely a portion of a butcher's skewer.

In the first case, in addition to the operation for the removal of the tuberculous tumor, a plastic operation was performed in order to close a laryngeal fistula. The patient is suffering from pulmonary disease, and lately this disease has been rather progressive. In the course of the violent coughing a small abscess formed in the lower angle of the external wound, which did not, however, communicate with the larynx.

Dr. Powers asked Dr. Gerster whether the microscopical report showed that the entire tumor had been removed.

Dr. Gerster said he could not answer this affirmatively, because examination as to that point had not been made, as it would have necessitated mutilation of the specimen; he could only say that everything that appeared diseased and somewhat more had been removed.

Dr. J. Mount Bleyer said that he had operated in some hundreds of cases, and that in a case of stenosis due to cicatricial tissue, which he had been dilating for the past four months, he had just been able to remove the tube, and he expected that it would not be necessary to reinsert it. He emphasized Dr. Brown's statement of the advantage of intubation in giving time for internal medication. A trial of this operation should always be given before resorting to other means.

Dr. James E. Nichols asked Dr. Gerster whether the tubercular process appeared secondarily in the larynx, and whether or not he had seen cases where the tuberculosis appeared primarily in the larynx which he considered proper for surgical interference. He had had several cases under his care in which the tubercular process appeared to him to come primarily in the larynx, and they all terminated fatally.

Dr. Gerster replied that he considered all cases of laryngeal tuberculosis to be secondary, and he believed primary tuberculosis of this organ to be extremely rare. The fact that we could not prove the coexistence of tuberculosis of the lung should not be accepted as proof positive that such process did not exist. He had seen it very frequently since the time when we learned to recognize the true nature of many surgical complaints formerly called strumous, and now known to be tubercular. He was in the habit of methodically making a careful examination of the internal organs on taking charge of a new case of local tuberculosis, and had often been unable to

find the slightest trace of lung trouble. He referred to a case of a man of extremely stout build, a wine-merchant, who came to the hospital for tuberculosis of the testicle. He admitted having had syphilis, and, in order to test the question in the usual fashion, large doses of iodide of potassium were administered for some time without any positive result. Dr. Gerster made an exploratory incision, deciding to castrate if the disease proved to be tuberculous.

It was found to be a typically tuberculous testicle, with emulsification of cheesy foci. The patient received ether during anæsthesia, and as a result of the consequent profuse salivation and secretion of mucus a pulmonary catarrh developed, and the man lost much flesh within a fortnight. An examination at this time revealed condensation in the apices of both lungs, which could not be detected while the thick masses of adipose tissue were present previous to the operation. Now the catarrh is perfectly typical of tuberculosis. Previous to an operation we cannot always establish the presence of pulmonary tuberculosis, but if a localized tuberculosis is found somewhere else in the body we may expect that, later on, the pulmonary affection may crop out. He did not doubt that in all these cases we have to deal with cheesy bronchial glands, this being the focus from which, as we all know, tubercular material is distributed throughout the body.

Dr. Kitchen expressed his personal preference for tracheotomy over intubation in laryngeal stenosis. He had seen quite a number of cases of tuberculosis of the larynx, and his treatment aimed simply at securing good nutrition of the tissues surrounding the formation, so as to make them as firm and resisting as possible. In most of these cases he objected to intubation, because it would not allow a continuous observation of the larynx, and might cause some irritation.

The Chairman said that he had had an opportunity of examining the case of tuberculosis of the larynx which formed the basis of the evening's paper a month or more before it came under Dr. Gerster's care. At that time he found a swelling, entirely localized, involving the left arytenoid cartilage and extending slightly forward and laterally toward the pyriform sinus. The tumor pitted on pressure, and when cocaine was applied it was diminished about one-third in size. He thought it due to one of three conditions, viz.: (1) An abscess due to a foreign body; (2) a perichondritis or caries of the cartilage; or (3) a new growth. Tuberculosis did not suggest itself to him at that time, owing to the rarity of such a lesion involving only one cartilage. On the supposition that the swelling was inflammatory, he had scarified it several times with the laryngeal lancet. The inflammatory reaction after this was not remarkable; there was some increased difficulty in deglutition. He had heard nothing about the case until some time after Dr. Gerster's operation.

About six weeks ago another case came to him, and the laryngeal appearances were almost identical with those in the first case. The swelling was much larger, involving the left arytenoid as in the other, and the swelling was so great and the dyspnœa so urgent that the patient was kept at his office until he could be transferred to the hospital. Four-fifths of the laryngeal cavity was occluded by this swelling, and it was expected that tracheotomy would be necessary. Steam and hot compresses were used very carefully, but the swelling seemed to be increased by them.

Ordinarily, in these cases, he considered the use of cocaine not altogether safe on account of the reaction, the original swelling being increased. Happily, in this case, cocaine did exceedingly well, and under continued treatment with a five per cent. solution—followed by an application of iodoform—the swelling steadily decreased, until now the patient breathes quite comfortably. The swelling is so much reduced that the affected arytenoid is nearly the size of the other. The patient says he has always been hoarse, and attributes his severe dyspnœa to catching cold.

Whatever the character of this growth—and it is quite possibly tubercular—it behaves well under treatment. He has general bronchitis and the cachexia of a phthisical subject, but no localized pulmonary deposit has been discovered. In regard to the feasibility of removing such growths by external operation, it depends upon the urgency of the symptoms, dyspnœa, etc. I strongly advocate mild endolaryngeal treatment first, as in my second case cited. A laryngotomy will surely develop pulmonary phthisis if the predisposition is present.

In regard to intubation as a substitute for preliminary tracheotomy, in the case of removal of laryngeal growths, the speaker cited a case in his practice of a young child with multiple papilloma. He had removed the growths but they had speedily returned, and the case was so difficult to operate upon that he had decided to perform thyrotomy. Dr. O'Dwyer was associated with him in the case, and it was the intention to pass O'Dwyer's snare into the larynx and remove the tumors. The child was given chloroform preliminary to a thyrotomy or tracheotomy, but he choked up so rapidly that there was no time for tracheotomy. In this emergency, Dr. O'Dwyer slipped in one of his tubes and waited a moment for the breathing to improve, after which his snare was introduced and the growths removed by scraping each side of the larynx with it. Three times intubation was required on account of the child choking up with blood and the débris of the growths. This case well illustrates the value of intubation as a substitute for tracheotomy under such circumstances.

Dr. Gerster said, in closing the discussion, that his main object in coming before the Section was to bring more prominently before the profession the value of an operation which he believed was not performed as frequently as it ought to be. It was not a question alone of giving the patient air for the time being; there was another problem to be solved, and that was the ultimate cure of the case. As an illustration, he referred to the cases presented that evening. In the case with the foreign body, would intubation or preliminary tracheotomy have done that man any service? It would have given only temporary relief, but the foreign body would have remained where it was. In a case like that of the multiple papilloma—one given up as hopeless by the laryngologists—we could treat it undoubtedly with much more satisfaction if the larynx were wide open and excision were performed, as it can be done with more precision than is possible when done through the oral cavity. He reiterated the statement that the cure of laryngeal tuberculosis had been accomplished, and that the results of treatment of this condition had become brilliant in comparison with those formerly observed. In his case, however, we did not have to deal with diffuse tuberculosis, but had a very rare form of the malady with formation of a large tumor which occluded the larynx, and at the same time produced intense dysphagia, and, as the further development of the case has shown, both symptoms have been removed by the operation. The patient has no tube in his throat and he is perfectly comfortable excepting for the pulmonary trouble. If the operation has only helped to make this man temporarily comfortable, and has saved him from the horrible and prolonged suffering due to dyspnœa and inanition which usually precedes the death of such patients, it has accomplished a good deal.

He felt much indebted to Dr. Brown for some details in the history of his case after it had been transferred to the service of his colleague. He denied, however, that dilatation by the use of O'Dwyer's tube had cured the case, as Dr. Brown had confidently claimed, for he believed it was accomplished by the expectoration of those bony particles which had been exhibited. Had these been removed before, the cure would have been effected without the introduction of the tube, or the reopening of the trachea by tracheotomy. He did not wish to be understood as not appreciating the value of these tubes, for his faith in this brilliant American method of treatment had

been amply proved by his declining during the past three years to perform tracheotomy for croup in children.

We are not to treat this question from the stand-point of tuberculosis of the larynx in general, but we are to deal with a tuberculous tumor of the larynx which is causing dysphagia and dyspnœa.

SECTION IN SURGERY.

Stated Meeting, February 11, 1889.

ROBERT ABBE, M.D., CHAIRMAN.

DIVISION OF THE FLEXOR TENDONS AND ULNAR NERVE AT THE WRIST.

DR. CHARLES A. POWERS presented a young man who, two and a half years ago, suffered a severe lacerated wound at the wrist, severing the flexor carpi radialis, the flexor carpi ulnaris, the palmaris longus, and the ulnar nerve. The wound was sutured by a physician who afterward brought the patient to the hospital, and said he had neglected to suture the tendons and nerve. Two days after the injury Dr. Powers saw the patient, and brought together the ends of the tendons and also of the nerve. At that time there was complete anæsthesia of the portion of the hand supplied by the ulnar nerve, and also loss of motion. Deep union resulted, although superficial union did not. Six days after the nerve was sutured the patient complained of great hyperæsthesia in the corresponding parts, which gradually passed away. Sensation in the parts had now become normal. Motion, however, had not returned in the interossei; he could abduct and adduct the fingers only very slightly. It was the rule that sensation in such cases returned much sooner than motion. Dr. Powers called attention to the great necessity of obtaining primary union in wounds at the wrist-joint, for if the wound healed by granulation the tendons became bound and the functional result was poor. Flexion in this patient had became about normal, but he was still unable to make full extension. Persistent use and electricity had brought about the result.

DR. AGRAMONTE showed the results of a wound which he had sustained in the right thumb many years ago from a bullet. All the structures except a portion of the integument were divided. The army surgeons advised amputation, but at his request applied a splint, and union took place. No sutures were used. By persistent use he had regained very nearly normal function. He had also sustained a division of the extensor tendon of one of the fingers by a sabre-wound, and in that case also the hand was simply put on a splint, and normal function returned. The speaker emphasized the importance of beginning motion in the parts as soon as the wound commenced to heal.

THE CHAIRMAN remarked that the result was likely to be better in division of the extensor than of the flexor tendons, their webbing allowing of less retraction.

DR. POWERS remarked on the importance of obtaining primary union, from which he had much better results.

REPRODUCTION OF THE ENTIRE PATELLA AFTER NECROSIS AND REMOVAL BY OPERATION—FUNCTION OF THE JOINT FULLY RESTORED.

DR. V. P. GIBNEY read the paper and presented the patient, a boy, who at the time of injuring the knee by a fall was seven years of age. Pain and swelling followed, and eight days after the injury a physician opened an abscess at the knee in the prepatellar region. A drainage-tube was inserted, and two weeks later Dr. Gibney saw the patient. There was then much discharge of pus, the parts were infiltrated, and the patella was movable over a limited area. The drainage-tube was not removed; a posterior splint was employed, and the case was treated as one of traumatic suppurative periostitis. A few days later he explored the parts after removing the drainage-tube. The probe touched bare patella. April 5th, the boy was anæsthetized, the patella turned out, the cavity washed with corrosive-sublimate solution, a counter-opening was made, a drainage-tube passed through, antiseptic dressing applied, the knee immobilized by plaster of Paris, and the boy kept abed three weeks. Convalescence was uneventful. In July the function of this, the right knee, was nearly as perfect as that of the left. The patella was now as large as that on the left side.

Dr. Gibney had reported a case of reformation of the patella after removal in a boy whose trouble began with acute articular rheumatism in 1877. The functional result, however, was not that obtained in the other case. It impressed the necessity for prompt surgical interference before the suppurative process extended to the joint. Removal of a part of the patella, and even of the entire bone, was not very rare, but the results in the patient shown were unique.

THE CHAIRMAN remarked that the condition described by Dr. Gibney seemed analogous to that of acute subperiosteal abscess with exfoliation in long bones, with reproduction of bone. The periosteum being raised from the bone by pus, the bone dropped out, and was replaced by new bone developing from the periosteum.

DR. SHERMAN, of San Francisco, said the late James R. Wood had a case of necrosis of the patella, removal of the bone and reproduction, but without restoration of function in the joint. The specimen was in the Wood Museum of Bellevue Hospital.

TUMOR OF THE CHEEK; QUESTION OF DIAGNOSIS.

DR. ROBERT T. MORRIS presented the specimen, a tumor, mostly solid, which had developed in the integument in front of the lobe of one ear, after an attack of scarlet fever, in a man. The parotid and deeper tissues were not involved.

The Microscopist pronounced the tumor malignant, but was unable to classify it as one of typical epithelioma.

Dr. Morris presented a second specimen from a case of doubtful diagnosis, being that of a patient who entered Dr. McBurney's service at St. Luke's in January, 1887, with apparently a tumor of the left lobe of the liver. Dr. McBurney made an incision an inch and a half long over the swelling, put in a trocar, drew off a quantity of pus, and introduced a drainage-tube. In April the discharge had increased, and in July the walls of the cavity were scraped with a sharp spoon. Dr. Morris saw the patient in July, 1888. He then had a fistula below the margin of the rib on the right side, discharging pus, and leading into a large cavity. He made a long opening into the abdomen near the median line, introduced the entire hand, and found a fibrous mass as large as one's fist attached to the lower border of the liver and to the omentum and intestines. Not being able to remove the fibrous mass entire, he opened it and readily peeled out a pyogenic sac which was lined with thin, calcareous plates, resembling the scales of the garfish. Inside were concretions the size of a robin's egg. The fistulous tract did not heal; another pyogenic sac formed, lined with calcareous matter.

THE CHAIRMAN said that in the intervals of Dr. McBurney's service at the hospital he saw this patient, and thoroughly scraped out the pyogenic membrane, but it refilled with the calcareous plates. He thought that originally it was a case of abscess of the liver.

RESECTION OF THE KNEE-JOINT; ORGANIZATION OF THE BLOOD-CLOT.

DR. A. M. PHELPS read the paper, and exhibited diagrams illustrating the methods which he had pursued in twenty-one cases of excision of the knee. A few years ago he had adopted the method recommended by Schede, of securing organization of the blood-clot after excision.

The histories of two of the typical cases were given in detail. The first was a case of ostitis of the tibia in a girl, which went on to invade the knee-joint. The limb became flexed at a right angle, the disease continued active, and he performed excision. After cutting the head of the femur and of the tibia away as far as possible with-

out entering the shaft, he found the abscess extended still deeper, and required scraping until but a shell of the head of the tibia and of the lower end of the femur remained. The bones were then brought carefully together, wired, the Esmarch bandage removed, the cavity allowed to fill with clot, and after three weeks, when the dressing was first removed, union both of bone and soft parts was found to have taken place; the union between the bones was evidently fibrous at that date. The second case related was similar.

To obtain a satisfactory result from organization of the blood-clot, it was necessary to observe rigid antisepsis. The Esmarch bandage prevented hemorrhage during the operation. Do not apply rubber gauze, which tissue was most commonly placed over the cavity, but use Lister's protective; over this apply antiseptic gauze, then absorbent cotton, then plaster of Paris to fix the joint, and afterward swing the limb. Bichloride was used, but the cavity should be entirely free from this antiseptic before the final dressing. In twelve of the twenty-one cases there was firm bone-union; in six there was slight motion, and consequently fibrous union; in one there was much motion, necessitating a posterior splint; two patients were still in the hospital, the sinus extending into the thigh, although primary bone-union had been obtained at the joint. The average time of confinement after the operation was four weeks, while usually union took place in two or three weeks. In nineteen of the cases he employed Fenwick's method, cutting the bone in a curved line. A rubber drain was used, extending only under the skin, not into the bone-cavity. He wired the bones together with silver wire in three cases; with iron wire in eleven, with or without a screw; in six cases no wire was used. The antiseptic was bichloride of mercury, 1 to 2,000 at first, afterward 1 to 5,000. It was absolutely necessary that the limb be kept quiet. The mortality from this operation was much less than from amputation, being less than four per cent. He was unable to tell why rubber tissue was not favorable for the organization of the clot, and in the course of the discussion said that he believed Schede did not claim originality for the method attributed to him.

Dr. R. T. Morris thought the term organization of the clot was improper, for there was annihilation and replacement by other tissue. Lister's protective was by far the best dressing. The epithelial cells developed from the clot were for some time stained with blood-pigment, but after a time the white scar appeared. If carbolic acid were used the blood-clot would break down. Bichloride was best, but none should be left in the wound.

Dr. Ridlon and the author discussed the indications for excision of the knee, and both agreed that it should not be performed in children under eight or ten years of age, as in them there would be too great shortening of the limb later in life. Dr. Phelps said there was usually less than an inch of shortening in cases adapted to the operation, and hardly ever more than two inches.

The Chairman thought this operation did not represent typical organization or replacement of blood-clot, since the clot was enclosed by integument; a typical illustration was seen in cavities of the long bones where the edges of the skin could not be brought together. He could not understand why Lister's protective should be superior to rubber tissue.

Dr. Van Arsdale believed that Schede recommended the use of a large drainage-tube to let out overflow of blood after the cavity filled. The necessity for this would probably be less urgent when the limb was swung, as in Dr. Phelps' cases.

Adjourned.

A New Departure in Surgery.—In a London hospital a woman, sixty-eight years of age, with scirrhous cancer of both breasts had them both removed simultaneously by two surgeons, one on each side of the table. The whole operation lasted forty-five minutes, and after a short time she was discharged well.

Correspondence.

OUR PARIS LETTER.

(From our Own Correspondent.)

ELECTROLYSIS FOR STRICTURE OF URETHRA—OPINIONS PRO AND CON—STRICTURE OF ŒSOPHAGUS TREATED BY ELECTROLYSIS—ELECTRICITY AS A TEST FOR DEATH—CADAVERIC RIGIDITY THE SURE SIGN OF DEATH—THE MODIFICATIONS OF THE BLOOD OF NERVOUS ORIGIN—CEPHALOTRIPSY AND THE CÆSAREAN SECTION.

Paris, March 22, 1889.

With reference to the correspondence in The Medical Record on the treatment of organic urethral stricture by linear electrolysis, the following note may be found interesting. A work on the same subject by Dr. J. A. Fort was recently submitted to the Academy of Medicine, in which the author, who has a large private clinic in Paris, chiefly devoted to diseases of the urinary organs, points out the advantages that this new procedure possesses over internal urethrotomy, dilatation, and divulsion, which are employed for the cure of the stricture of the urethra. Electrolysis is an operation absolutely inoffensive, whereas he considers that urethrotomy is a dangerous operation, often giving rise to fatal accidents. The operation with the electrolyzer is performed without previous dilatation, or any other preparatory treatment. It is performed without causing any pain, and in four or five minutes. Even the narrowest strictures may thus be operated upon at once, and the operation is never attended with hemorrhage nor followed by accidents. It requires no further treatment, and the patient may be allowed to follow his occupations without inconvenience. Relapses are extremely rare. This, however, does not accord with the experience of Dr. Lavaux, who also has a large clinic for diseases of the genito urinary organs. At a recent meeting of the Academy of Medicine the author read a note on the distant results of linear electrolysis in the treatment of urethral stricture. According to his experience, some of the patients were cured for a time only, and more frequently relapses were rapid. Of thirty-five cases operated on with the electrolyzer, the radical and permanent cure has never been obtained. Dr. Lavaux prefers rapid dilatation to all the other methods in the treatment of stricture of the urethra.

At the meeting of the Academy of Medicine on the 13th instant, Dr. Dujardin-Beaumetz presented, in the name of M. Fort, a patient affected with stricture of the œsophagus, which M. Fort operated on, assisted by Dr. Brochin, the well-known surgeon, by his procedure of urethral electrolysis. The stricture, which was operated on on the 16th of February, then measured five millimetres in diameter, but when the patient was presented it measured fourteen millimetres. The patient, who arrived from the provinces, and who was dying from inanition, was scarcely able to swallow even a few drops of liquid, but since he submitted to the operation he is able to take all sorts of nourishment. On his arrival in Paris, on the 16th of February, he weighed 114 pounds, he now weighs 123 pounds. This is the first time that linear electrolysis has been applied for the cure of stricture of the œsophagus. The success is considered complete.

A writer in the *Journal de la Santé* considers that the verification of death by the aid of electricity is the only serious method, and the most easy to practise. The most elementary of electric machines suffice for this purpose, and any person can apply it without difficulty. The muscles of the face being the first to lose their contractility (the muscles of the eyelids and of the lips excepted), if, with an apparatus which determines, on the arm of an assistant, a slight contraction, no contraction whatever of the muscles of the face is produced, one might affirm that the person is dead. Should the slightest trace of contractility be observed, the same apparatus should be,

without delay, employed to electrify the region of the heart, and if death is only apparent, one might thus, in restoring the action of the heart and the respiration, restore the subject to life. In this manner one would avoid the sad accidents analogous to such as recently occurred in the provinces. A lady at Coutras was about to be interred, when, at the last moment, it was perceived that she was only asleep.

In connection with this subject I may cite the summary of a long memoir recently addressed to the Academy of Medicine by Dr. Bernard, of Saint Germain-en-Saye, on the signs of death and on precipitate inhumations. The author concludes that the verification of deceased persons is a formality generally neglected by municipalities, particularly by those in the provinces, and that henceforth not only the inhabitants of communes, but also school-children, should be taught the prescriptions relative to burials. According to Dr. Bernard, the only infallible signs of death being cadaveric rigidity and putrefaction, the medical man should only deliver his certificate when he has established the presence of these phenomena. Cadaveric rigidity being liable to occur before death, it is prudent to wait for the first sign of putrefaction, viz.: the greenish coloration of the abdomen.

At a recent meeting of the Société de Biologie, Dr. Féré made some observations on the modifications of the blood of nervous origin. He stated that in a certain number of hemiplegic and hysterical patients he found that the number of red globules were augmented in the vessels corresponding to the anæsthetized or paralyzed limbs. He also found that in these same vessels the quantity of oxyhæmoglobin was less considerable, and that the duration of the reduction of this oxyhæmoglobin at the ungueal surface was longer. These facts are in perfect concordance with those brought to notice by Dr. Malassez and other authors, viz., that the number of red globules diminishes in the dilated vessels and augments in the contracted vessels. At a subsequent meeting, Dr. Féré read a note on the modifications of the blood in epileptics. He examined the blood of a certain number of epileptics before and after the attacks. He found that after the fits the number of hæmatics and of globulins were augmented, and that the red globules were easily altered.

At a recent discussion at the Société de Chirurgie, on the relative merits of cephalotripsy and the Cæsarean operation, Dr. Bouilly related the case of a rickety woman on whom he had performed the Cæsarean operation about a year ago. At a previous pregnancy he had to perform cephalotripsy in the same patient. The subpubic diameter was only six and a quarter centimetres. Dr. Bouilly made an incision in the uterus of sixteen centimetres, and brought into the world a female child of three kilogrammes. The hemorrhage was considerable, but the uterus retracted under the effect of two hypodermic injections of ergotine, and the wound of sixteen centimetres was reduced to eight centimetres. Eight deep sutures, with silver wire placed in the muscular tissue, and eighteen superficial points of suture reunited the peritoneum to the surface of the uterus. With the view of preventing future fecundations Dr. Bouilly put in practice a procedure till then unknown, he tied up the two Fallopian tubes with two ligatures. The patient had not the least febrile reaction, and is now in good health, as is also her child.

The fourth session of the Congrés Français de Chirurgie is to be held from October 7 to October 13, 1889, at Paris, under the Presidency of Baron Larrey. The following questions are to be discussed: 1. The immediate and distant results of operations practised for local tuberculoses. 2. The surgical treatment of peritonitis. 3. Treatment of aneurisms of the limbs.

The second session of the Congrés International d'Hydrologie et de Climatologie will be held at Paris, from October 3 to October 10, 1889. The members, national and foreign, will be required to pay a subscription of 20 francs. The committee calls particular attention to the questions above indicated. The greater part of these questions will each be the object of an *exposé* or of a report, which will be published, sent to all the members three months, at least, before the opening of the Congress, and will serve as a starting-point for discussion at the sittings of sections. Other works concerning hydrology and climatology may be submitted to the Congress. Authors are requested to send to the Secretary of the Congress the titles and conclusions of their memoirs at least one month before the opening or the Congress.

THE TREATMENT OF LOCOMOTOR ATAXIA AND OTHER SPINAL DISEASES BY SUSPENSION.

To the Editor of The Medical Record.

SIR: Since the latter part of February, I have been treating a number of cases of locomotor ataxia and of other chronic spinal disorders by suspension, according to the method described by Motchoukowski, and popularized by Professor Charcot.

The treatment has been tried in six cases of locomotor ataxia, and in one of Friedrich's disease, also in paralysis agitans, transverse myelitis, hemiplegia, and sexual neurasthenia, sixteen cases in all. The suspensions were made with a Sayre apparatus; they were given three or four times weekly, beginning with half a minute, and extending to over three minutes.

The results so far obtained are these: In one ataxic, sixteen suspensions, there was improvement in subjective feelings in the lower limbs and a steadier gait, no other change. In a second ataxic, ten suspensions, slight improvement. In a third ataxic, who was suffering intensely from lightning pains, no improvement after seven suspensions. In the other ataxics a few suspensions have been made only. The patients say that they feel better and freer in the legs for a day.

In the cases of paralysis agitans one patient felt much better after two suspensions; and it gave him so much relief that he used to hang himself from the top of the door at his home several times daily. He has had eight suspensions.

The second patient, after nine suspensions, thinks his stiffness somewhat improved. The most enthusiastic seeker for suspension is a patient with transverse dorsal myelitis. After thirteen suspensions he really seems much benefited in freedom and strength of movement. The same remark applies to a patient with cerebral hemiplegia who has had nine suspensions. The case of Friederich's disease claims to feel better than he has for a long time.

Of the value of the treatment in functional weakness of the spinal centres I cannot yet speak.

The original description of the effects of this method of treatment was given by Dr. A. Motchoukowski in *Vratsch*, Nos. 17–21, 1883. He reported fifteen cases of locomotor ataxia, in the first stage, treated by suspension; thirteen were improved, showing less pain, parasthenia, and increase of muscular strength, but no cure was pretended.

Dr. Motchoukowski also tried the treatment in cases of lateral sclerosis, multiple sclerosis, and diffuse myelitis, without success.

He describes also some experiments which were made to determine the mode of action of the treatment. On suspending a cadaver he found a lengthening of the body of 6 ctm., a lengthening of the spine, between the second cervical and fourth lumbar vertebra, of 2½ ctm. He noted the increased arterial tension, increased rapidity of pulse and respiration in suspending living persons, and was inclined to explain the improvement in his cases by the greater activity of the circulation induced during suspension.

I have noticed, as would be expected, exaggerated reflexes (in those who haven't ataxia) during suspension. The circulation in the arms is impeded, and the pulse often can not be felt at the wrist.

Dr. Motchoukowski suspended his patients for ten minutes, three or four times weekly. This, it seems to me, is not always necessary or safe. Orthopædic surgeons have learned that adults are liable to faint after long suspensions.

Suspension does not seem to act so well upon very tall and heavy persons. It may cause for a day or two a slight pain in the small of the back, which soon disappears.

The number of suspensions necessary must vary very much with different cases. Half a dozen or a dozen accomplish all that can be accomplished in some cases.

Suspension may do actual harm, and its application and dosage require some care.

The method of treatment of tabes by suspension is not an irrational one. It gives a slight stretching to the nerves, and gives an impulse to a better circulation in the cord. It is usually harmless and it is easy of application. It is applicable chiefly in the first stage of tabes. I have seen enough of it to feel assured that it is a method of treatment inferior in importance to others in our possession. It is a measure of minor and occasional value.

I have now made over one hundred and twenty-five suspensions in sixteen cases.

Dr. R. Saundby has reported several cases in which he has used suspension with moderate success only.

M. Abodie reports the best results in cases not typically atoxic.

My own experience is corroborated by others, therefore, who place a less value on the method than is attributed to it by Charcot.

I believe from some experiments already made, that better results, as far as some symptoms go, may be had by partial suspension by the heels.

I am under obligations to Dr. William P. Wilkin for the care and attention in carrying out the details of the treatment.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 6, 1889:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	10	3
Scarlet fever	408	64
Cerebro-spinal meningitis	9	5
Measles	144	14
Diphtheria	187	49
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

"THERE'S NO HARM DONE."—The following song is said by the *Hospital Gazette* to be popular just now among medical students of Dublin and London. There is a good deal of a moral in the lines:

I extracted the wrong tooth, but there's no harm done;
I like to tell the truth, when there's no harm done.
The patient never knew if I pulled one tooth or two,
And he still has got a few, so there's no harm done.

I once made a patient lame, but there's no harm done,
And he'll never be the same, but there's no harm done.
He thinks it was his fate that he took advice too late,
For a train he's often late, but there's no harm done.

I put out a patient's eye, but there's no harm done;
He thinks it was the fly, so there's no harm done.
In place of Atropin I dropped in Winter Green,
But, of course, it wasn't seen, so there's no harm done

Once I gave too big a dose, but there's no harm done;
I request you'll keep it close, but there's no harm done,
Up the medicine he threw, or shouldn't I look blue,
What I tell you is quite true, and there's no harm done.

THE OCCURRENCE AND MECHANISM OF PHYSIOLOGICAL HEART MURMURS (ENDOCARDIAL) IN HEALTHY INDIVIDUALS.[1]

BY MORTON PRINCE, M.D.,

PHYSICIAN FOR NERVOUS DISEASES, BOSTON CITY HOSPITAL.

SUMMARY.—Frequency of these murmurs as determined by study of 77 normal subjects. They are endocardial and functional, not organic. Coexisting cardio-respiratory murmurs. Analysis of concomitant physical phenomena. Increased cardiac action a causative factor. Mechanism of the heart by which the mitral orifice is closed, as determined by recent experiments. Relation between this action and mitral murmurs. Murmurs due to weakness of the mitral sphincter. *Physiological leakage may occur from a normal sphincter being forced by excessive muscular action—these murmurs are of this nature.* Characteristics of these murmurs the same as ordinary regurgitant murmurs. Permanency. Frequency of aortic and pulmonic murmurs. Theory of their mechanism. Alternative hypothesis. Appendix.

For a number of years past I have been in the habit of examining physically all the applicants for positions in the Boston Fire Department. Almost without exception, those seeking these positions are in the prime of life, that is, on an average twenty-five years of age, and, as a rule, are a hardy and muscularly tough-looking class of men. I have been consequently much surprised at the frequency with which heart murmurs have been present at the time of examination. As these men have all the appearance of health, and upon close questioning deny all symptoms in any way suggestive of heart disease, as well as antecedent conditions likely to lead to it, such as rheumatism, I have been at a loss to understand the frequency with which I have been able to detect the presence of a murmur. To be sure, the conditions under which testimony as to the past and present health of these witnesses is given are sufficiently trying to the sternest conscience to make one take all statements *cum grano salis;* but, nevertheless, as will presently appear, heart murmurs are far too frequent to attribute them to disease, even including anæmia or functional weakness.

At first I was in the habit of ascribing these murmurs to the excessive use of tobacco, to which men of the firemen class are, if not universally, at least as a rule, addicted. But this theory I have been obliged to abandon, believing that tobacco plays a secondary part, if any.

In order to determine more accurately the frequency and character of these murmurs, I lately recorded the condition of the heart in a large number of cases, taking them consecutively as they appeared. I have notes in 86 cases in all. In every case the sounds at the apex, over the mitral and tricuspid valves, and at the aortic and pulmonic orifices were carefully examined, as well as the position of the apex-beat.

In many cases, not in all, the sounds over the larger arteries, viz., subclavian and carotids, were examined whether valvular murmurs existed or not. All these cases are tabulated below, and the sounds heard in each region noted. But, while all adventitious sounds over the valves of the heart have been noted in every case, so that if, in any given case, no murmur is recorded, it may be understood to be absent, the same is not true of the sounds heard over the arteries. The frequency of sounds in these situations would appear much greater if they had been noted in every case. Owing to the limited time at my disposal, and as they are not of pathological significance, I did not always examine for them. I should state, however, that they are of very common occurrence in these cases, a fact which, as will presently appear, is of some importance in determining the mechanism of these murmurs.

The whole number of cases recorded is 86; of these there were other indications of organic disease, than the mere presence of a murmur, in 9. Excluding these, we have 77 cases in which the heart was apparently healthy. But of these 77 a systolic murmur could be detected in the mitral area in 25.[1]

Whole number recorded	86
Evidence of organic disease in	9
	77
Systolic "mitral" murmur in	25
No "mitral" murmur in	52

It will be noticed that in the accompanying table (I.) a systolic aortic murmur is frequently recorded, but for the present I wish to confine myself to the mitral murmurs alone. I am conscious of the fact that the frequency of this murmur in these cases is so great that some little scepticism is likely to be aroused regarding the accuracy of the observations. But I can say that no one can be more solicitous on this point than I have been myself. The "personal equation," that unbidden guest that sneaks into our laboratories and clinics, and confounds the senses of the keenest of mortals, is particularly fond of playing pranks with observations of this sort. Everyone who does not wish to deceive himself must admit that what may be a murmur to him may be a normal sound to another; or, given a mind in a state of expectancy, a subjective murmur is readily heard.

To determine whether errors of this kind could have been introduced, I have made comparative tests of my own ear in detecting murmurs with the ears of a number of other gentlemen, but have not found that we have differed regarding the quality of any given heart-sound.

Besides this, Dr. Garland, at my request, has kindly examined with me a number of the cases in my tables, and in every case agreed with me as to the existence or non-existence of a murmur. Further than this, although in the habit of examining the hearts of a large number of men weekly under other conditions, I do not find murmurs with any particular frequency elsewhere, nor do many of the murmurs that I do find seem to me to be of the same character as these. These murmurs, I must insist, are in my experience peculiar to the class of men with which I am dealing, that is, men strong, hardy, and in the prime of life, examined under conditions of nervous excitement, without any reason to suspect existing disease. I do not, as I have said, find murmurs of similar character with equal frequency elsewhere, and feel, therefore, additionally justified in believing that my observations are correct, and that the "personal equation" is not here a disturbing factor.

[1] Read at the annual meeting of the Boston Society for Medical Improvement, January 14, 1889.

[1] Cases 10 and 13 are excluded as being questionable.

TABLE I.

No.	Apex sounds.	Aortic orifice.	Pulmonic orifice.	Left auricular region.	Subclavian arteries.	Right carotid artery.	Pulse.	Heart's action.	Cardiac area.	Remarks.
1	Soft, blowing, high-pitched systolic, tr. to left.	Systolic		Systolic				Violent.		
2	Systolic, soft, blowing, tr. to left			Systolic		Harsh systolic.		Violent.		
3					Systolic.					
4		Systolic			Systolic	Slight and temporary.				
5	Soft, faint systolic						72			
6	*Soft systolic, loudest in third and fourth interspace, one inch to left of nipple.*	*Systolic and diastolic.*				*Systolic*	68	*Natural*	*Normal.*	
7	Soft systolic, tr. to left; loud also at fourth rib and third space close to sternum.		Faint systolic.	Faint systolic.		Systolic	75	Forcible.		
8					Right and left systolic.		81	Rather violent.		
9					Right and left subclavian.		69	Natural.		
10	Rough first sound (murmur?) at junction of fifth and sixth ribs with sternum; tr. to right, slightly to left.						90	Rather violent.		
11	Soft systolic, tr. to left; disappeared, then reappeared.				Right systolic.		81	Violent.		
12	Loud, soft systolic, tr. to posterior axillary line; heard behind below left scapula.			Systolic			96	Forcible		Murmur over left auricle traced downward with increasing intensity to apex.
13	First sound at apex impure, systolic.						96	Strong.		
14						Systolic	75	Violent.		
15		Systolic			Left systolic.					
16	Soft systolic				Left	Systolic	93	Violent.		
17							96	Strong		Normal.
18					Left and right.		102	Not violent.		
19							81	Natural		No murmurs.
20						Systolic	90	Forcible, violent?		
21							84	Natural		No murmurs.
22	*Soft systolic; loudest on f. e.; slight on f. i.*			*Soft systolic.*			88	*Violent*	*Enlarged*	*Apex beat in sixth space, inside mammillary line. At a later examination the murmur (apex) had disappeared.*
23					Right and left.	Systolic? temporary.			Natural.	
24	Soft systolic; loudest at fourth space, close to sternum on f. e.						111	Violent.		
25	*Blowing systolic, tr. to left*	*Systolic*				*Systolic*	72	*Markedly irregular.*	*Normal*	*Murmurs unaffected by respiration excepting less loud at f. e.*
26							75	Natural		No murmurs.
27	Momentary systolic on f. e.; f. i. lost.				Left		80	Strong.		
28							75	Natural		No murmurs.
29							63	Natural		No murmurs.
30	Soft systolic; f. i. lost; f. e. diminished; m. e. loudest.	Slight rough systolic.					69	Forcible.		
31		Systolic			Left		69	Forcible		Aortic murmurs probably transmitted from subclavian.
32	Soft systolic, tr. to left; f. i. lost; f. e. diminished or lost; m. e. loudest.	Systolic			Left and right.		66	Strong		Aortic murmurs probably transmitted from subclavian.
33							84	Forcible.		
34							63	Natural		No murmurs.
35							78	Strong.		
36	Loud, soft systolic, tr. to left; heard at fourth left space; f. e. loud; f. i. lost; m. e. less strong.		Systolic	Systolic			99+	Forcible.		
37	Soft systolic, tr. to left; f. i. loudest; f. e. lost; m. e. faint.	Faint systolic.				Distinct systolic.	84	Strong		Aortic murmurs probably tr. from carotid
38							84	Strong		No murmurs.
39	Systolic, tr. to left and below left scapula; also a second higher-pitched cardio-respiratory murmur during inspiration.	Systolic			Right and left.	Rough systolic.	114	Violent.		
40	Temporary systolic, also cardio-respiratory.			Not examined.	Not examined.	Not examined.				
1	Faint systolic (no cardio-respiratory).			Not examined.	Not examined.	Not examined.	93	Strong.		
42	*Systolic, tr. to left; heard at back; very loud over fourth rib near sternum; cardio-respiratory murmur.*	*Systolic*		*Not examined*	*Not examined*	*Not examined*	66	*Natural*	*Enlarged*	*Apex in mammillary line.*
43	Systolic, tr. to left; heard at back, and tr. to aortic orifice.	Systolic			Not examined.	Not examined.	99	Violent	Apex close to and inside mammillary line.	
44–47										
48	Loud systolic, heard at back; tr. to left; present during f. e., f. i., and m. e.; heard also over aortic valves.	Systolic					81	Violent		Normal. Nervous.
49	Faint but distinct systolic.						90			
50							60			No murmurs.
51	*Squeaking systolic over mitral area.*		*Rough systolic.*				(?)	(?)	*Enlarged*	*Pulmonic second sound accentuated.*
52	*Systolic and cardio-respiratory.*			*Not examined*	*Not examined*	*Not examined*			*Enlarged.*	
53		*Systolic*		*Not examined*	*Not examined*	*Not examined*				*Organic.*

NOTE.—Tr. = transmitted; f. i. = forced inspiration; f. e. = forced expiration; m. e. = medium expansion. Italics indicate probable organic disease. Cases are not in the order in which they were examined.

TABLE I.—*Continued.*

No.	Apex sounds.	Aortic orifice.	Pulmonic orifice.	Left auricular region.	Subclavian arteries.	Right carotid artery.	Pulse.	Heart's action.	Cardiac area.	Remarks.
54.	*Systolic and heard at back; also cardio-respiratory of different pitch; former tr. to anterior axillary line.*	.....	.....	*Not examined.*	*Not examined.*	*Not examined.*	*98*	*Violent*	*Slight enlargement.*	*Apex can be felt in mammillary line.*
55.	Cardio-respiratory only on full inspiration.	.....	.....	Not examined.	Not examined.	Not examined.				
56–59.	.....	.....	.....	.....	.....	.....	....	.....	.....	Normal.
60.	*Systolic, moderately loud*	*Occasional systolic.*	*Systolic*	.....	.....	*Systolic*	....	.....	*Apex beat in mammillary line.*	
61.	Moderately loud systolic, tr. to left; heard over mitral valve and at apex.	.....	....	.....	.....	Systolic.				
62.	Faint systolic.....	.....	Systolic	.....	Systolic	Systolic.				
63.	Loud systolic, tr. to left	.....	.....	.....	Systolic	Systolic.				
64.	Soft systolic, tr. to left, and from apex to left auricle.	Faint systolic.	Systolic	Systolic	Systolic	Systolic	120	Violent; excited.	Normal.	
65.	.....	.....	....	.....	.....	Systolic	99–102	Not especially violent.

71–75.	.....	.....	.....	.....	.....	.....	....	... .	....	Normal.
76.	Soft systolic, which after one to two minutes disappeared.	.....	.....	.....	.....	....	69	Strong.		
77–86.	.....	.....	.....	.....	.....	....	....	.....	.....	Normal.

NOTE.—Tr. = transmitted; f. i. = forced inspiration; f. e. = forced expiration; m. e. = medium expansion. Italics indicate probable organic disease. Cases are not in the order in which they were examined.

Furthermore, after these observations had been made I mentioned, in a general way, to Dr. McCollom that I met with murmurs with surprising frequency under the above conditions, but did not communicate the exact results; in fact, at that time I had not tabulated my notes. Dr. McCollom kindly offered to note the frequency with which he found these murmurs in his examinations of men for the police. He now tells me that, as a result of his entirely independent observations, he has found "functional mitral regurgitant murmurs" present in twenty-seven out of two hundred men.'

He has kindly offered to bring his notes (which I have not yet seen) here to-night.

Although this frequency is not equal to that with which they have been present in my experience, yet it is sufficient to be regarded as confirmatory evidence on the part of an entirely independent observer of the great frequency of these murmurs.

For what discrepancy exists I think I can, in the proper place, offer satisfactory reasons.[1]

The most interesting part of this subject is the mode of production and significance of these unusual heart-sounds. That they are not due to a diseased condition of the heart is apparent from the very frequency with which they occur. It is preposterous to suppose that twenty-five out of every seventy-seven men, with every appearance of health, have heart disease, and that, too, without existing pathological signs; or even that they are suffering from those temporary disturbances of health, such as anæmia, which are known to cause the murmurs ordinarily understood and recognized as functional.

These murmurs, then, must be physiological, not pathological.

CARDIO-RESPIRATORY MURMURS.—A certain number of them undoubtedly may be cardio-respiratory. There are two kinds of cardio-respiratory murmurs; one is due to the forcible expulsion of the air from the lung by the heart striking against it. It will be remembered that the tongue-like expansion of the lung—the lingula pulmonis—overlies the left apex. When the heart is beating vigorously, this portion of the heart is liable to be compressed against the chest-wall. The air is consequently driven out and a systolic murmur is produced. It is soft, blowing in character and resembles the expiratory murmur in pitch and quality. It persists during quiet expiration and inspiration. It is usually loudest when the lung is moderately full of air and during quiet respiration. It generally diminishes in intensity and may disappear when the air is forcibly expelled from the chest. The reasons for this are obvious. This exocardial murmur is often difficult to distinguish from a true endocardial bellows murmur. The points of differentiation are its pitch and quality, its behavior during inspiration and expiration, and its seat of greatest intensity being not directly over the apex but to the left, in the mammillary line, *i.e.*, over the lung. When another murmur of different pitch is present, the two are easily distinguished. It is difficult to deny that some of the murmurs recorded in the tables as mitral may be of this character, some of them without doubt are,[1] but it is out of the question to suppose that more than a minority can be accounted for on this theory.

The second variety of cardio-respiratory murmurs is due to the suction-action of the heart on the lungs. With each cardiac contraction the bulk of the heart is reduced in size, and a corresponding vacuum produced in the chest. This is compensated for by a corresponding expansion of the lungs—a sort of cardiac respiration, as it were. If the heart's action is strong, it is easy to understand how the in-rushing air, with each systole, would produce a murmur synchronous with the first sound of the heart; but this murmur should resemble in pitch and character the inspiratory sound of the lungs—and this is exactly what is the case. Usually it is a quick, short accentuation of the inspiratory sound, synchronous with the systole of the heart—a sort of jerky, inspiratory sound; but as this reenforcing, respiratory murmur occurs only with the first sound of the heart and ceases during diastole, it gives the impression of being endocardial, whereas it is really exocardial. At least, such is the most probable explanation. These cardio-respiratory murmurs are usually easily distinguished, and one learns to disregard them almost unconsciously. They occur only during inspiration, and are devoid of the characteristics which we shall find belong to the mitral murmurs above recorded. That they occur only during inspiration is probably due to the fact that the suction power of the heart is not able to act on the lungs when they are retracting during expiration; that is, inspiration and expiration cannot take place at the same time. That they diminish or cease when the breath is held, it seems to me, is due to the fact that under these conditions they fail to be re-enforced by the normal inspiratory sound.[2]

[1] Since published in the Boston Medical and Surgical Journal, January 31, 1889.

[2] See Boston Medical and Surgical Journal, January 31, 1889, p. 109.

[1] See Appendix.

[2] As a rule, these murmurs were neglected and not recorded in these tables.

RAPIDITY AND FORCE OF THE HEART'S ACTION.—In a certain number of cases—I am sorry to say, not in all—the pulse-rate and action of the heart were noted. When the latter seemed to be normal it was so classified, or as "natural;" when it seemed to be above the normal it was noted as "strong," forcible," or "violent," according to its apparent strength. The pulse-rate is recorded in 43 cases, as follows:

Over 75 in 29, { souffle[1] in 13, none in 16.

Under 75 in 14, { souffle[1] in 6, none in 8.

It will thus be seen that souffles were not of greater frequency when the pulse-rate was increased than at other times. It is worth noting, as showing the degree of nervous excitement present, that pulse-rates of 90 and upward were not uncommon, even 120 being recorded, and that 29 out of 43 were over 75 shows to what extent nervous excitement existed.

When we come to take into consideration the force of the heart's action, a different state of affairs is met with. The heart's action is recorded in 42 cases, as follows:

"Strong," "forcible," or "violent," 29, { souffle in 17, none in 12.

"Natural"..... 13, { souffle in 1, none in 12.

Or a mitral murmur was present in fifty-eight per cent. of the cases when the heart's action was above the normal, and in only eight per cent. when the action was "natural."

Taking the converse of this, the same fact is emphasized still more strongly.

Of the whole 25 cases in which a mitral murmur was detected the heart's action was noted in 20, as follows:

20 cases, { action "strong," "forcible," "violent," 19, "natural"..... 1.

In observing the character of the heart's action it was impossible not to be struck with the difference between the strong, vigorous thump in the cases marked "strong," "forcible," and "violent," and the commonplace beat of the average heart. There was as much difference between them as there is between the musculature of an athletic young man of twenty-five and that of an old man of sixty. It was just such an action as might be expected in a vigorous heart working under nervous excitement.

This increased muscular action furnishes the key to the explanation of these murmurs; but to understand this it will be necessary to briefly study the mechanism of the mitral valve.

MECHANISM OF THE MITRAL VALVE.—The first thing that strikes us on referring to the common text-books on anatomy and physiology is the inexactness and speculative character of our knowledge as therein laid down regarding the closure of the mitral opening—an inexactness which in consequence is naturally shared by most medical men. The conception of the mitral valve usually entertained by practitioners generally, and that described in most of the books, is that the mitral opening, bounded by a ring of fibrous tissue, is of fixed and unvarying diameter, and that the opening is closed by the mitral flaps alone, in one or other of the various ways described in text-books. It is also usually laid down that the base of the heart does not diminish in size during systole.

Foster, in the fourth edition (1880) of his work, for example, states that, "according to Kurschner, the circumference of the base of the ventricle is absolutely increased during systole."[2]

It is owing to what must now, in the light of comparatively recent experiments, be regarded as erroneous notions of this kind, that the meaning of many mitral systolic murmurs have not been understood.

[1] A mitral souffle only is referred to.

[2] In the latest edition of his Physiology, now in the course of publication, Foster has modified his description of the heart's mechanism in accordance with later experiments.

Hesse,[1] by a series of ingeniously devised experiments, has shown that the mechanism of the heart is very different in some important respects from that usually supposed. As these experiments are only beginning to find their way into text-books, and are not generally known, it will be necessary for me to briefly describe them here.

Hesse contrived to obtain casts of the heart during diastole and systole, and, by taking puppies of the same size and weight from the same litter, to obtain hardened hearts of the same size, in both diastole and systole, from which sections could be made. The details of the experiments I will not go into here, but merely give the results of his observations.

The accompanying diagrams (Figs. 1 to 3) are taken from his work, and illustrate the points of importance in this connection.

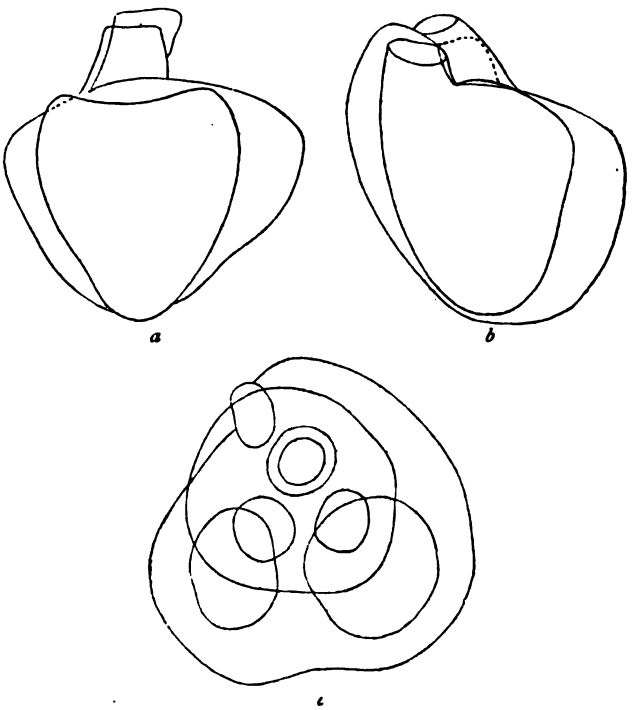

FIG. 1.—Outline of Hearts of Two Puppies of same Size and Weight in Systole and Diastole. *a*, Posterior surface: *b*, left side; *c*, base. The difference in size of auriculo-ventricular openings in systole and diastole is plainly shown in cut. The pulmonic and aortic openings are taken as fixed points.

In the first place, he showed that the area of the base of the heart in the plane of the auriculo-ventricular valves, so far from remaining constant in systole and diastole, is enlarged more than one-third in the latter condition.

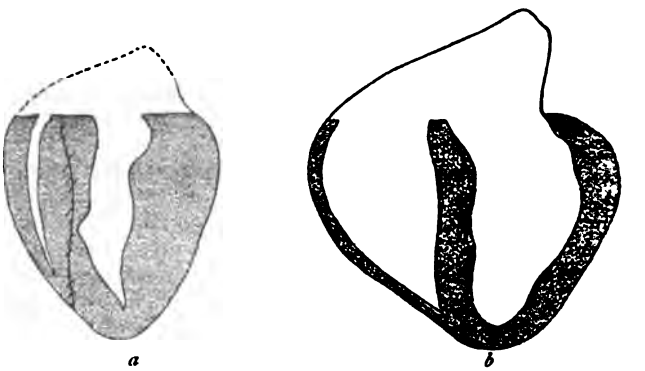

FIG. 2.—Frontal Sections showing Cavities in *a*, Systole; *b*, Diastole. (The perpendicular line drawn through the septum in *a*, was drawn through error of engraver.)

Secondly, the mitral orifice, so far from being of constant size, dilates with the expansion of the base and is constricted during systole.

Thirdly, a point of interest, but one with which we are-

[1] Archiv. f. Anat. und Entwickelungsgeschichte, 1880. For an account in English see article by McAlister, British Medical Journal, October 28, 1882.

not directly concerned, is that there is no shortening of the ventricle (left) during systole, as has been claimed.

In other words, during diastole the auriculo-ventricular orifice is too large to be closed by the mitral valve alone, but must be first constricted by the muscular contraction of the base, and that then only the valves suffice to close the opening. The valves may be said to be a size too small for the hole.

The arrangement of the muscular fibres of the heart is calculated to accomplish this action. Although the arrangement of the fibres is, in detail, very complicated, Hesse shows that they may be practically separated into three layers; an outer one of diagonal, a middle one of circular, and an inner of longitudinal fibres (Fig. 4).

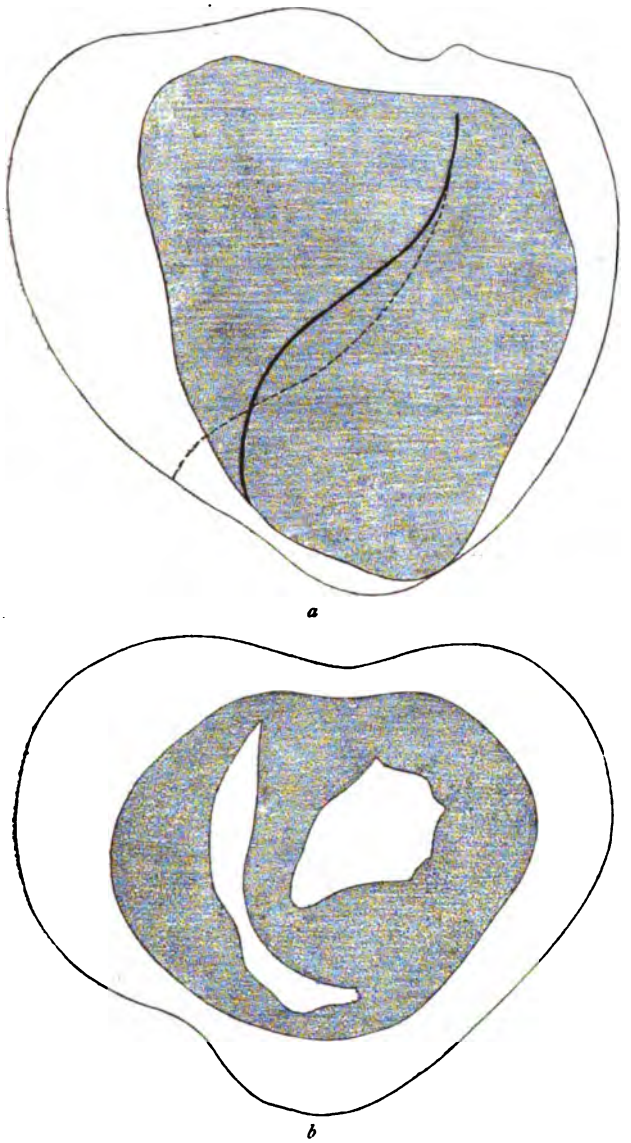

FIG. 3.—Outline of the same Dog's Heart in Systole and Diastole. *a*, Seen from the front; *b*, from the base.

Accordingly, the closure of the mitral orifice is effected by two actions. First, by the sphincter-like action of the circular muscular fibres, and, second, by the apposition of the valve-segments.

The effect of the sphincter-action in narrowing the orifice is very beautifully shown when looking into the aperture of the ventricular opening from the auricle. Owing to the puckering of the circular basal ring to which the valves are attached, these appear to be made up of four or five segments instead of two. A comparison of this drawing from Thompson (Fig. 5), with a similar view in Quain, will show this more clearly. Dr. William G. Thompson has succeeded in obtaining a very beautiful series of instantaneous photographs of the heart in action. Some of these are reproduced here. These photographs seem to correspond with Hesse's casts, and show the same diminution of the area of the base during systole (Figs. 6 and 7).

In the light of these experiments many mitral regurgi-

FIG. 4.—Section through Heart, showing Three Layers of Fibres.

tant murmurs assume a new meaning. The murmurs that occur, for example, in the course of acute fevers, of diphtheria, typhoid, and probably also in many cases of acute rheumatism, though once explained by hypothetical changes in the blood, are really regurgitant murmurs caused by weakening of the mitral sphincter. The same

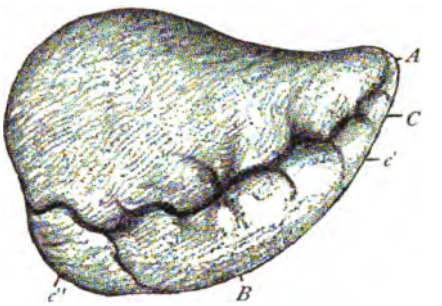

FIG. 5.—Mitral Valve of Bullock, Closed, as seen from Left Auricle, showing Line of Apposition of Cusps and their Uneven Surface. *A*, large cusp ("aortic cusp"), attached near aortic valve; *B*, next largest, or "parietal cusp;" *C*, *c'*, *c''*, lesser cusps filling in the angles between the larger ones.

condition of affairs also probably obtains in chlorosis and that form of general debility brought on by degenerating diseases, like chronic diarrhœa and malaria, and also by continued hardships and wear and tear of life. Mitral regurgitant murmurs are very common under the latter

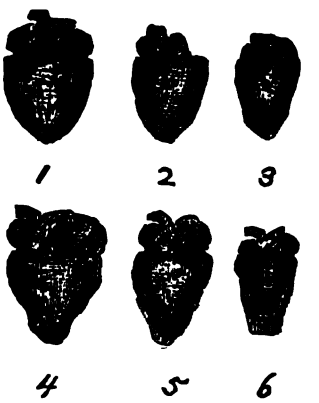

FIG. 6.—Photographs of the Heart in Motion. 1, Normal diastole; 2, auricular systole; 3, ventricular systole. 1, 2, 3 were taken in a half second; 4, 5, 6, same as 1, 2, 3, after injection of toxic dose of strophanthus hispidus. 4, 5, 6, were taken in a half second. The pulse-rate was 74. (Thompson.)

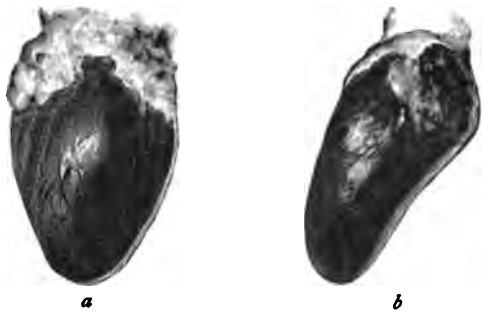
conditions. It is also apparent how a slight degree of dilatation may give rise to regurgitation, what before was not so clear so long as the basal area and the mitral openings were considered constant.

This form of regurgitation may be said to be now fairly well recognized, and has been termed "curable mitral regurgitation" (Balfour).

Now it occurred to me that the converse of this might be true, namely: *Given a normal, healthy sphincter, with excessive pumping action on the part of the heart under strong nervous excitement, and a temporary leakage might occur, from the blood being forced through the sphincter in spite of the action of the latter.*

Under ordinary conditions the sphincter and the valves are sufficient to prevent leakage, but theoretically it is evident that under excessive muscular action the sphincter might be forced.



a *b*

FIG. 7.—Pigeon's Heart in Motion. *a*, Full diastole; *b*, full systole, produced by application of hot salt and water. (Thompson.)

The question before us is, Do the cases here tabulated present evidence to show that this practically occurs? or, put in other words, Is there reason to believe that this is the correct explanation of these cases?

I have already shown that one factor, increased muscular action, is present. Further evidence on this point may be obtained from the arterial murmurs that coexist in many cases, and which are so commonly heard in physical examinations of this kind.

I regret that I did not examine for a record these arterial murmurs in all cases. But, as with many other points, not having any theory in mind when the observations were made, I failed to do so.

Of the twenty five cases, a co-existing arterial murmur is noted in twelve.[1] I say noted, because, as has been said, these murmurs were not always looked for. These arterial murmurs must be regarded as indicative of increased cardiac action. Some years ago I made some observations to determine the frequency and rationale of these murmurs. These notes have been lost, but I remember that they were very common.

A noteworthy case, illustrating the extreme type of this kind of action of the heart, with the murmurs that must be regarded as the effect of it, is Case 64.

Here there existed a soft systolic murmur at apex, transmitted to left and from apex to left auricle; faint aortic systolic; pulmonic systolic; left auricular systolic; subclavian systolic; carotid systolic (faint). Pulse, 120; heart's action "violent, excited."

Case 54 is interesting as showing, it seems to me, an exaggerated condition of this same condition. It is excluded here because there was slight enlargement present. Though the apex-beat to the eye was in the normal position, pulsation could be felt in the mammillary line. I had another opportunity to examine the case a few weeks ago.

A systolic murmur could be heard at apex, transmitted to left as far as anterior axillary line, and heard beneath the left scapula. A cardio-respiratory murmur of different pitch, heard during inspiration, was also present. Heart's action violent, pulse 93.

I have since learned that this subject belongs to a neurotic family, and that both he and his brother have previously had some form of neurosis. The regurgitation in this case is probably due to temporary dilatation of the heart, due to relaxation of the muscle, and represents the curable form.

Further evidence in favor of our hypothesis is derived from the character of the murmurs. If they are really regurgitant sounds they should present the character of sounds due to this cause. A study of the records shows they do so.

1. They are heard loudest at the apex.

2. They are transmitted to the left, sometimes as far as the posterior axillary line.

3. Sometimes they are heard in the back beneath the scapula (this was not always looked for).

4. A murmur of similar character is sometimes heard over the region of the left auricle and pulmonic region, and sometimes can be traced upward to this point from apex.

5. They are sometimes heard equally loud at the junction of the fourth rib and sternum on left side, *i.e.*, over the mitral valve.

6. The effect of holding the breath after forced expiration (f. e.), forced inspiration (f. i.), and during mean expansion (m. e.), was observed in seven cases. In only three cases did they disappear under the first of these conditions. Sometimes they sounded louder. As a rule they were diminished by forced inspiration; occasionally increased. As a rule, I should say, taking into account other cases not included here, they were louder during mean expansion.

The bearing of this test lies in the fact that some authorities assert that exocardial murmurs disappear after forced expiration, while endocardial murmurs persist. I am not disposed to lay too much stress on this test.

Finally, the association of these murmurs with murmurs elsewhere is interesting as showing the character of the heart's action as a whole.

Summary.—Total, 25 cases. Heart's action increased in every case but one where noted. Aortic murmurs in 9. Pulmonic, or left auricular, or both, in 8. Arterial in 12.

Further light is thrown on the mode by which regurgitation of this kind may be brought about by the experiments of Thompson just referred to, and by some still later experiments of Waller.

The former has shown, by means of photography and the application of different stimulating substances, that the reserve contractile power of the heart is from one-quarter to one-half; that is, that under such stimuli the diminution of the size of the heart may be one-half greater than during normal systole; to which we must add, assuming that normal systole is represented by that obtained under the conditions of physiological experiment, when the heart is exposed.

Waller[2] concludes, from observations on certain electrical phenomena connected with cardiac pulsation, that the ventricular walls do not contract as a whole, but the contraction begins as a peristaltic wave at the apex, progressing upward. If this be so, it is still more easy to

[1] Case 27, in which the mitral murmur was only transitory, is not included; an arterial murmur coexisted.

[2] Balfour, following Naunyn, maintains that the basic murmur heard in chlorosis and other conditions is loudest over the left auricular appendix (that is, an inch and a half to left of sternum in second intercostal space), and is really a mitral regurgitant murmur transmitted to this region through the dilated appendix.

[2] British Medical Journal, October 6, 1888.

understand how a physiological regurgitation might take place, for a powerful peristaltic contraction, beginning at the apex, might easily force blood through the mitral sphincter before the latter had time to act.

Professor H. P. Bowditch, in conversation with me, has suggested that the probability of the ventricles contracting in this way might be inferred from the thinness of the walls at the apex. If the apex did not contract first, it is probable that the wall at this point would not be able to withstand the internal pressure, and rupture would frequently occur.

Regarding the *permanence* of the mitral murmur, I find that in four cases it is noted that they disappeared at the end of the examination. It should be said that I could not systematically examine for this point, but from the general impression produced by my earlier experience as a whole, I suspect that if attention were specially directed toward determining the fact, most of these murmurs would be found to disappear after the heart had quieted down. I can recollect in the past several cases which I had an opportunity to re-examine at different intervals. The murmurs in these cases disappeared.

Aortic and Pulmonic Murmurs.—I have less to say in regard to these. There can be little question that they must be looked upon as due to the violence of the heart's action. It must be a matter of mere luck that the passage of the blood through the aortic and pulmonic orifices is ordinarily soundless. It must be a matter of mere chance that a certain harmony exists between the size of the cardiac chambers, the outlets, and the force of the current, as a result of which no sonorous vibrations sufficient to reach the human ear are ordinarily produced. I say sufficient to reach the human ear, for it is possible that such vibrations of low intensity occur, and, if our ears were keen enough, could be detected. For "sonorous fluid-veins are always generated when the blood-stream passes *with sufficient force* from a part of the circulatory system which is actually or relatively constricted into a part which (in comparison with the part behind it) is actually or relatively dilated." This condition of affairs practically obtains at the aortic and pulmonic orifices. We have a large ventricular cavity, a non-yielding orifice, and a yielding dilating tube, leading from the latter. With every systole the aorta and pulmonary artery expand and become relatively dilated in comparison with the aortic and pulmonic orifices, which are consequently relatively constricted. If the blood-stream passes with *sufficient force*, a murmur must result.

It is practically the same condition of affairs that exists in mitral regurgitation.

One factor stands out prominently in all cases as requisite, namely, a certain intensity of blood-current, and if the passage of the blood through the aortic and pulmonic orifices is ordinarily soundless it must be because the force of the stream is too weak.

I cannot help thinking that, after all, this simple explanation is the correct one for the functional basic murmurs about which so much controversy has been waged, and so much romantic imagination expended.

I give here a table, showing the association of these murmurs with others.

Table III.—*Aortic Murmurs.*

Summary.—Twelve cases. In every case, where noted, the force of the heart's action was increased. Mitral murmur in 9 cases. Arterial murmur in 8 cases. Mitral or arterial (or both) in every case.

It is proper to state that no inference should be drawn from this table as to the *relative* frequency of these aortic murmurs, as in some cases it must be regarded as doubtful whether the murmur originated at the aortic orifice, even though plainly heard there. In some of the cases it is likely that it was transmitted from the carotid or subclavian. In the time at my disposal it was impossible to determine this accurately.

Summary.—Total, 8 cases. Heart's action increased in every case where noted. Mitral murmur in every case. Aortic murmur in 3 cases. Arterial murmur in 5 cases.

* These two murmurs are tabulated together on account of their proximity and possible unity.

Alternative Hypothesis.—If this be not the correct explanation of these mitral murmurs, the only plausible alternative hypothesis that remains is that they are not endocardial, but exocardial, the cardio-respiratory theory already referred to. These cardio-respiratory murmurs are very easily detected when they have the characteristics already described, namely, when they occur only during inspiration, cease on expiration, and when the breath is held; are of the same pitch as the inspiratory murmur, and appear as jerky accentuations of the same, synchronous with the heart's systole. If the respiratory hypothesis be maintained as explanatory of all the mitral murmurs here described, then I know of no way of differentiating between an endo- and an exo-cardial murmur, for both would have the same characteristics. Again, the respiratory theory will not explain both murmurs in those cases where two could be detected of different pitch, one of which can be proved to be cardio-respiratory, *e.g.*, Cases 39 and 40.

I have thus far refrained from extending my conclusions to other conditions than those under which these observations were made. But I think we shall not transgress the canons of probability if we go further, and apply this explanation to murmurs heard under various other conditions. It is not difficult to understand how almost any disturbance of cardiac muscular action may give rise to regurgitation of a similar character—if the mitral sphincter is temporarily weakened relative to the pumping portion of the heart, or if the latter be increased relatively over the former; or if, through disturbance of nervous energy, a lack of harmony exists in the action of the different parts of the cardiac muscle, then regurgitation may take place. It seems to me that most of the so-called functional murmurs heard during systole at the apex will be found to be due to agencies of this kind. Such murmurs are usually temporary, and probably give rise to the contradictory opinions given by physicians to one and the same patient.

If these observations are correct, and the conclusions well founded, I cannot help thinking that they will prove of practical value, not only in our offices, but in passing upon applicants for life insurance, the civil service, and perhaps college athletics.

Appendix.—Curiously enough, while these studies were being made, Professor Roy and Mr. Adams, in England, were pursuing a somewhat similar line of inquiry, on the experimental side, in the laboratory. Their paper[1] came to my knowledge too late to be incorporated in the text, but as these most interesting experiments throw a great

[1] Failure of the Heart from Overstrain, British Medical Journal, December 15, 1888.

deal of light on the mechanism of the heart action under certain conditions, it will be interesting to briefly refer to them here, especially as they, within certain limits, throw light upon the conclusions here reached from the clinical side. These experimenters undertook a series of experiments on the effect upon the heart of variations in the work which it is called upon to perform in conditions of health and disease. The mechanical work done by the heart is determined by the amount of blood thrown out in a given time and the pressure against which it is thrown. We have then to deal with the effect of changes in these two factors. Changes in the blood-pressure were induced by narrowing the aorta at one or another part of that vessel. The effect of this upon the heart is, first, to increase the intra-ventricular pressure, the pressure having a maximum limit. With fatigue of the heart—produced either by continued slight narrowing, or often repeated great narrowing—this maximum limit gradually falls. Secondly, such narrowing of the aorta produces a very evident distention of both ventricles, which nevertheless go on contracting and expanding in what, to the eye, seems a perfectly normal manner; but examination of the veins shows that (thirdly) regurgitation is taking place through both the mitral and tricuspid valves. Increase in the total quantity of blood in the vascular system also increases the work done by the heart. More blood is expelled, diastolic expansion is greater, and the degree of contraction less. Within physiological limits there is no great harm in such variations in the diastolic expansion of the heart, which are very much greater than is generally supposed. The extent and the efficiency of contraction is increased, although the degree of contraction of the individual muscle-fibres at the end of systole is diminished. Although the conditions under which these experiments were performed were different from those existing in the cases which form the subject of this paper, the facts elicited are to the point so far as they demonstrate the physiological variations that may normally take place in the size of the heart, as well as the physiological regurgitation that may take place in the auricles from the ventricles when the organ is called upon to do increased work. Whether increasing the work done by stimulation of the vagus and accelerans produces the same result, is not stated, but left for a further communication.

The possibility is at once suggested, however, that in the cases recorded in the foregoing tables a slight dilatation may be present as a result of increased heart action. A physiological regurgitation would thus be more easily induced.

Several cases I have seen suggest this. The following is particularly in point. It was that of an applicant whom I rejected one year ago. The mitral murmur was loud and the heart was slightly enlarged, the apex-beat being displaced toward the left. I sent the man to a specialist, who confirmed my opinion of organic disease. A few days ago the man, by chance, returned to me, and I could find nothing abnormal. The only change he had made in his habits was to give up tobacco, of which he was a heavy chewer. He had had no cardiac symptoms. Since this paper was written I have had an opportunity to examine 85 more men, with the above theory in mind, omitting the cases in which organic disease may have been present. In 24 individuals a systolic murmur was present at the apex, but in 10 of these it seemed to me that the murmur might be accounted for as exo-cardiac, that is, cardio-respiratory; so that in 14 cases there was a true endocardiac murmur. In the first 56 subjects I examined the heart first, as was my custom in the earlier series. In the last 29 subjects the heart was examined last, and time given to the applicant to become accustomed to the ordeal. In these last 29 a true endocardiac murmur was heard only three times, and a cardio-respiratory once; while in the preceding 56 subjects an endocardiac (mitral) murmur was heard eleven times.

This shows that the conditions of the examination have much to do with determining the frequency of the murmur.

Dr. McCollom tells me that in a second series of 111 men, he detected a mitral systolic murmur in 18 individuals.

It seemed to me, too, that I was frequently able to detect a slight enlargement, such as might correspond to that following increase of the work done in the above-mentioned experiments. But I will not speak positively in this matter until I have made more precise examinations.

A SUCCESSFUL CASE OF IMMEDIATE RESECTION OF THE INTESTINE FOR GANGRENE.[1]

By ROBERT H. M. DAWBARN, M.D.,

INSTRUCTOR IN OPERATIVE SURGERY, NEW YORK POLYCLINIC.

It gives me pleasure to lay before the gentlemen of this Section of the Academy a case of exceptional interest to us all, that of a recovery after immediate circular enterorrhaphy following excision of a large amount of dead gut, in a case of strangulated femoral hernia in an elderly lady. I shall be unable to be present at the May meeting, otherwise I would accept our Chairman's courteous offer to make this the principal paper at that meeting. To Dr. Powers I am indebted for the privilege of taking his time to-night, and my report, in consideration of the lateness of the hour, shall be as brief as possible.

The history of the case is as follows: I was called to see Mrs. M—— on Saturday evening, March 23d. She is, as her daughters say, "at least fifty-five years of age." She has had a rupture twelve years, for which she has worn a truss. Twenty-four hours before my visit, while sweeping, she was taken with severe pain in the region of the rupture. The truss frequently allowed the gut to descend, and now she could not reduce it. Vomiting immediately set in. Her family physician now attempted taxis, failed, used morphine by needle, and ordered a poultice. The poultice, which the family had applied, and which I saw, was of the thickness, hardness, temperature, and about twice the size of a silver dollar.

Four hours previous to my visit the vomiting, which had persisted and was frequent, became fecal in odor, and about that time, too, hiccough began and was very distressing. The local pain and tenderness continued.

On examination I found a hernia on the left side, about the size of a large fist, painful and tender, very tense, and without impulse on coughing. Gentle taxis failed. Poupart's ligament seemed to pass about to the middle of the tumor, and the parts being quite fat, I was in doubt whether I had to deal with a femoral or an inguinal hernia. The most fixed point of the swelling seemed the lowest, and this inclined me toward the former view, which proved correct. Her general condition was fairly good. The temperature was 100.5° F.; her heart and her kidneys seemed efficient.

I advised immediate operation, to which she agreed. The operation was begun two hours later, at ten o'clock P.M. I was assisted by Drs. F. A. Manning, H. J. Kelly, J. H. Brower Browning, and two of my students, Messrs. Brickner and Van Deusen. I wish at this point to say that I consider the good result largely due to the scrupulous care and attention of the surgeons named.

The entire pubic and inguinal region and both labia majora were shaven and the parts disinfected as usual. In all respects the usual care to secure absolute asepsis was observed, the details of which may well be omitted from this recital. I considered it very important to have a high atmospheric temperature. There was no stove or other heating appliance, nor any thermometer as a guide. I had the windows closed and lit many lamps and candles. The air was kept so warm that everyone present was freely sweating.

An incision was made, in the long axis of the tumor, its entire length. The sac upon being exposed was, of course,

[1] Read before the Surgical Section of the New York Academy of Medicine, April 8, 1889.

opened. I regard a surgeon who to-day reduces a strangulated hernia by operation without first opening the sac and examining the gut, as absolutely without justification. His only possible excuse is the peritoneal superstition, and this is born of dirt. The advantages of opening are too numerous to require mention here.

The moment the sac was opened a considerable mass of omentum protruded, and a small quantity of fluid of offensive odor escaped also. A large loop of the small intestine was found strangulated, almost black in color, and tense with gaseous and semifluid contents. Its peritoneal coat was smooth in most places, but there were a few small ruptures of this coat, possibly due to taxis. As was subsequently discovered, a small ulcer at the point of constriction, of some depth, threatened perforation, and a deep groove in the gut separated the sound from the unsound portion.

The constriction was very great—I cannot imagine it greater. To relieve it, I used, as the safest means that could be employed, the smaller blade of my French-lock blunt-pointed scissors, curved on the flat, and rather dull. This was cautiously passed, the convexity toward the gut, and then the edge being slightly turned toward Gimbernat's ligament, this was divided a sufficient distance to make circulation through the intestinal vessels entirely and easily possible.

Although the gut was not entirely lustreless, and was not sticky, I was convinced that it was dead. Upon pinching the gut sharply (after freeing the constriction) the very dark blood squeezed away by the finger and thumb did not return, even slowly. I determined to give it a chance, however, and nearly twenty minutes were spent awaiting a change in its state, the gut and the entire wound being meanwhile enveloped in soft cloths wrung out of warm bichloride solution, 1 to 10,000. At the end of this time no change whatever was noticed, either in the gut or in the color of the mesenteric vessels nearest it.

Under ordinary circumstances I should now have considered excision and a temporary artificial anus the best of the several means at our disposal.

To leave the gut out for hours, properly protected, or to return it to the abdominal cavity, under control by means of a tape through the mesentery, are measures only justifiable where the surgeon has reason to think intestinal life wavering in the balance; where, for example, pinching the gut shows a very slow return of blood to the pale spot so produced, but still a return. This temporizing exposes the patient to several obvious dangers, but in case of doubt must be selected.

For three reasons I decided in this instance to follow my kelotomy by immediate circular enterorrhaphy: First, my patient was in excellent condition, and could, I thought, under the careful anæsthesia then being conducted, bear a much longer operation. Second, the appearance and feel of the gut, with which I have had many opportunities to familiarize myself, convinced me that it was a part of the jejunum and not the ileum, and hence nutrition with an artificial anus would not be well maintained. Third, the patient's bowel above the strangulation could not contain much fæces, as a thorough movement had occurred a little more than a day previously, and nothing had been retained in the stomach since then. Consequently, great pressure from retained gut-contents would not be brought to bear against my intestinal sutures.

My first step was to ligate off with catgut the masses of omentum present, cut them away, irrigate carefully, and return the stumps to the abdomen. Next, several inches of healthy gut at each end of the dead loop were drawn out of the abdomen. The gut, its mesentery, and the wound were thoroughly irrigated. In order to protect the peritoneal cavity from infection, a long strip of iodoform gauze was packed around the gut in the bottom of the wound as firmly as was thought safe for the vascular supply. Then the mesentery was stitched, with cobbler's sutures of catgut, a distance exactly equal to that of the gut about to be removed, and on a line about two-thirds of an inch from the gut. This suture puckers the mesentery so that it is greatly shortened. Then the gut was cut with scissors, which next divided the mesentery as near to the sutures as seemed safe. Not only the dead bowel, but an inch or more of that which seemed sound was removed from each end, this step being really in the line of safety rather than recklessness. The amount removed in this way measured twelve and two-thirds inches. This I show here, together with a part of the omentum excised. An additional small piece of the bowel was cut away at one end, in order to make absolutely sure of perfect blood-supply from the mesentery, so that a foot and nearly an inch of intestine were lost to the patient. This, accepting as correct the lists of published cases, 115 in number, recently so carefully collected and elaborated by Dr. A. J. McCosh, is the largest amount of gut successfully removed at an immediate operation for strangulation on record in America.

One of the surgeons present now held the intestine firmly, so as to occlude it, about two inches from either end. These two inches were carefully emptied and irrigated, and then the ends approximated. The sutures employed were of catgut and interrupted, two rows being used, a Czerny and a Lembert.

In sewing the mucous and muscular coats especial care was devoted to the intermesenteric margin. This, for ease of work, should be sewn first of all. I placed a mesenteric stitch, not too tight, across the gap above the gut, on each side, to reinforce this weak point. The Lembert sutures, following Sir William MacCormac's wise advice, were so drawn as not to *force* the peritoneal surfaces together, but barely to appose them. I remembered, too, Dr. Wyeth's report of a case of his own, demonstrating that within three and a half hours after the operation the line of contact would be completely buried—hidden—and the sutures protected by a thick layer of fibrinous exudate.

The stitches were placed one-eighth of an inch apart, and were not superimposed, so that a suture was present, of each alternate kind, for each sixteenth of an inch. The needle used was a common, small cambric needle, which had been passed through a flame. After a final irrigation with 1 to 4,000 bichloride, the gut was returned to the abdominal cavity. The hernial sac, following the method of Mitchell Banks, was now dissected clean away, clear to Gimbernat's ligament, the freshly irrigated wound dusted well with iodoform, and rather firmly packed with iodoform gauze, which was carried up as far as the peritoneum, and a stout bichloride dressing applied.

The patient stood the operation remarkably well, there was little shock, the vomiting and hiccough ceased immediately, also the abdominal pain. A hypodermic of morphine with atropine was administered at once. No food whatever was allowed for twenty-four hours, and but little water. Thereafter, hot clam-juice for twenty-four hours, then matzoon, peptonized milk, and Rudisch's sarco-peptones, at the patient's option, for the first week. The bowels moved spontaneously and painlessly the second day. I have since twice moved them freely by a glycerin enema, but usually she has a satisfactory daily movement without medication. The temperature did not go above 101° F. (vaginal), but remained between 100° and 101° F. for five days, after which it became normal. The dressing has been twice changed. The wound is granulating and filling very rapidly. It is now between two and three weeks since the operation, and I can safely say that she is out of danger. At least two gentlemen here to-night have seen her within twenty-four hours, and can testify to her lively appearance.

Now, a few words regarding several points of interest, and I will end my paper. After so thorough and workmanlike and scientific a *résumé* of this topic as that recently presented to the Surgical Society by Dr. McCosh, together with a report of a successful case of his own, very little that you would care to hear remains for me to say. There are, however, some questions which suggest them-

selves, and on which I would especially like the opinion of those much more experienced than myself. First, as to sutures? I used catgut, and catgut has a number of times been used, notably in two recent instances of his own, reported by Dr. Briddon. But, I think, most surgeons advocate boiled silk. My catgut was taken direct from the solution which I always employ of late, and which, I think, keeps the gut aseptic and strong in a very satisfactory way, namely, a saturated solution of washed iodoform in sulphuric ether. I first immerse the commercial gut in ether to remove its fat, and after a few days put it permanently in the iodoform-ether. This is preferable to the ether-alcoholic solution, as the gut is kept equally as strong in the former, and iodoform is but feebly soluble in alcohol (1–80) as compared with ether (1–54). Dr. Nicholas Senn's demonstration, that by the time forty-eight hours have elapsed after the gut is sutured the cementing of the opposed serous surfaces is so great that even severe internal pressure will not part the lips of the wound, gives me confidence that there is no danger that the catgut used will be absorbed too soon.

As to the duration of anæsthesia, it was two and three-fourths hours. The actual suturing of the gut took nearly one and a half hour. This takes more time to do properly, with not a stitch too tight or too loose, too deeply or too superficially placed, than anyone realizes who has not tried it. I have demonstrated this operation now nearly fifty times, upon as many subjects, in my operative surgery classes at the New York Polyclinic, and it is always most tedious. Since speed is a tremendous factor in the problem of success in bowel-work, we shall all heartily welcome any device cutting short the duration of operation and yet giving a perfect result. It may well be that in Abbe's catgut rings (an improvement on Senn's plates, seeming equally safe and always ready at hand) we have the means of saving many lives through point of time. I have not yet had an opportunity to test the question as to the time needed to invert the gut ends, close each with Lembert stitches, point the overlapped ends in opposite directions (as Dr. Abbe has suggested, to get normal peristaltic waves), and opening the two sides apply the rings. I should think that quite a little time might be saved by this method as compared with circular enterorrhaphy. If the surgeon, however, deems it wiser to suture the ends by Czerny previous to inversion and the Lembert, then nothing, it would seem, would be gained. For sewing twice the diameter is equal to sewing two-thirds of the circumference of the gut; and it would probably take no longer, on the average, to put the double line of sutures into the remaining third of the circumference than to make the openings, insert the plates or rings, fasten them, and take the few Lembert stitches recommended for security.

In my case I was bothered a little by the fact that so much intestine was removed that there was quite a noticeable difference in the calibre of the two ends. Beginning at the intermesenteric point, and working round gradually, I had a little wrinkle in the larger end to overcome before completing the circle. In a future case I should avoid this by putting my second stitch just half-way round the circumference, my third and fourth midway between these, and so on. In other words, I should sew it according to the rule in other wounds, always dividing the spaces into halves by our stitches. After doing this completely by the Czerny, the peritoneal stitches could easily be placed.

The great length of gut excised precluded the possibility of taking a V-shaped piece out of the mesentery; and indeed I cannot see the advantage of this in any case. The time spent in suturing the edges of the mesentery is a needless prolongation of the operation, and so, I think, is the suturing of the edges of the mesentery after cutting it between the cobbler's sutures and the gut. It seems best, by way of preventing bleeding, to make these latter stitches before dividing either the gut or mesentery.

Just a word regarding irrigation. This, I think, should be nearly continuous during the sewing, and of simple warm water or salt water, in temperature at least 100° F. If very distinctly warm to the hands, say 105° or 110° F., the additional warmth will only have the soothing effect of a poultice; while, on the other hand, the slightest chilling of the gut would tend toward shock. For the same reason I think the heat of the operating-room, previously mentioned, to be essential in such cases.

In another instance I think I would scratch the peritoneum to be opposed, lightly, with my needle, to hasten agglutination, as recommended by Senn. This I did not think of at the time.

Finally, my good fortune in this instance is, of course, very largely due to the chance that I was called in early, strangulation having lasted but twenty-four hours. It seems evident that if prolonged taxis were avoided and very early operation always urged, there would be found extremely few cases of dead gut, and those few would show a much smaller mortality from excision than is the case at present.

STERILITY: INTRODUCING A NEW INSTRUMENT FOR ITS CURE.

By P. E. OUTERBRIDGE, M.D.,

ASSISTANT SURGEON TO THE WOMAN'S AND NEW YORK CANCER HOSPITALS; ATTENDING GYNECOLOGIST TO THE DEMILT DISPENSARY.

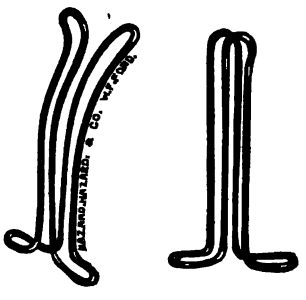
An apology may seem in order for drawing the attention of the reader to a subject which is touched upon in most of the gynecological text-books of the present day, and with which every gynecologist is supposed to be familiar. But at the present time there is a decided tendency to study with care only those things that are entirely new. I am aware that in taking up this topic I shall have to go over some old ground, but I trust, nevertheless, to be able to throw a little light on this rather old and threadbare subject. My connection with two of the largest clinics for diseases of women in this city has brought before me the frequency of the existence of sterility and its unhappy consequences, a condition the amelioration of which must be apparent to all; moreover, I have found it to be the fact that by a large majority of patients at the clinics sterility is often regarded with shame, not unmixed with a feeling of disgrace, ideas quite contrary to those entertained by patients among the better-educated class, in whom superior training has lessened these ancient convictions, for we know that among the old Romans a barren wife was considered a cause for separation. The patients, therefore, who come to consult for this condition often fail to mention the subject directly, in the hope that something may be done to bring about the possibility of conception. It is only, therefore, by close and careful questioning that we elicit from them the real object of their visit. There are so many obstacles to conception that might be present in the same person that in making a diagnosis of sterility in a particular case it often takes not only time but careful examination to ascertain its cause, and frequently it is arrived at only by exclusion. It must be understood that conjugation necessary for conception between the male and female may be imperfect, as I have in several instances had cases of this kind under observation, the trouble being with either the male or female, and sometimes both. Patients themselves will often attach much importance to a lack of participation, or so-called feeling, during coitus, but it is certain that sterility cannot with any justice be attributed to this cause, though many authorities still cite this as one. In cases that give this history some other reason is always found, but it is nevertheless possible that it may be due to some constitutional trouble which impairs the general condition, or from lack of food or exercise the parenchyma of the uterus and appendages is weakened and so rendered incapable of developing and sustaining a healthy ovum; but I believe this to be of rare occurrence. In my opinion the absence of proper conjugal feeling will almost invariably be found to be of local origin, and if diagnosed correctly and treatment be carried out intelligently, at least in seventy per cent. of the cases our efforts to cure will prove successful.

It must be remembered that sterility may exist in the male as well as the female, even though the sexual relation appears normal, and after a careful examination of the female, and no cause can be found for the existing condition, an examination of the male should not be omitted. I will not at present enter into detail as to how this should be conducted, but will simply state that with the microscope and other modern appliances a diagnosis can very easily be made. The reader can readily understand, if such a condition exists, it would be a great injustice to subject the female to prolonged treatment even if she have some slight trouble.

In arriving at a diagnosis the general practitioner is, of course, much handicapped, and I believe it is almost impossible, in a complicated case, for him to arrive at a definite conclusion, first, because he is not constantly associated with gynecological cases, and in consequence cannot handle the instruments with the same ease nor to such advantage as thes pecialist; and secondly, he probably has not the appliances that may be required to arrive at a certainty when a diagnosis has to be made by exclusion. The difficulty is, of course, due to the inaccessibility of the uterus and appendages, and, above all, to the fact that it is impossible to note the development and descent of the ovum through the tube into the uterus. Hence I would suggest that such cases should invariably be under the care of a specialist, for even he, with everything at his command, cannot always arrive at an absolutely correct diagnosis, and I fear that in many instances he is not led to look carefully enough for a cause for sterility, but is content with treating, in a general way, some slight misplacement, adhesive bands, or so-called pelvic inflammation, which may have existed for a long time, and which perhaps in themselves do not give rise to any symptom. If the misplacement be a lateral or forward one, their patience is apt to be exhausted before its correction can be accomplished. Even though the cause of the sterility be discovered, many of the patients will not submit to any surgical interference in the way of operative measures, as there has always been a good deal of mystery connected with the procreative functions, and they at once regard surgical interference as opposed to the natural order of things.

Recognizing the many difficulties to be overcome, first, in obtaining the history, and, next, in following out any of the lines of treatment suggested in the text-books, which, in many instances, are extremely difficult and in the end perhaps futile, I thought if some very simple means could be devised by which the two vital elements could at least be brought together the probability of the desired result occurring (viz., pregnancy) would be increased fully fifty per cent., and so solve this difficult problem. It is unnecessary at present to mention the various operations and surgical appliances devised to accomplish this simple thing, for the reader is doubtless perfectly familiar with them, and knows or believes that, in the large majority of cases, a successful result is not obtained.

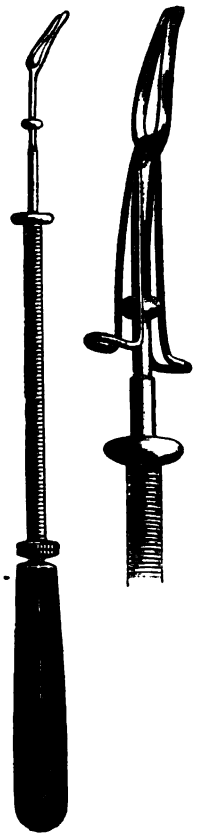
The instrument I introduce in the following cuts is a very simple affair, consisting of a continuous steel wire made so as to form an anterior and posterior blade, with a slight eversion at one end, and, at the other, is bent at right angles. This shape adapts it admirably for the position it is to occupy in the cervical canal. The instrument is entirely self-retaining, and, in consequence of its form, is not liable to change position. If, however, this should occur, it shows that it is not adapted to this special canal, and the operator can, with a small forceps, bend it to meet requirements. The dilator varies in length from one to three inches. The wire should be bent as desired, then tempered to give sufficient power, and heavily silver- or gold-plated. This makes it perfectly clean—in other words, renders it safe. The first instrument I made by simply taking a hair-pin and bending it into the required shape; this was used shortly afterward, being scraped and cleansed thoroughly with soap and water, and introduced with a plain dressing-forceps, the uterus being steadied by a tenaculum.



This primitive instrument, of course, is very much less effective, and apt to be even dangerous on account of its non-elasticity and possible accumulation of rust, whereas the present instrument is both yielding and aseptic.

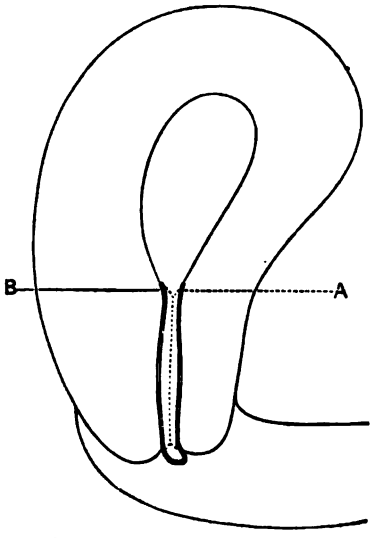
The patient was allowed to go home with this instrument *in situ*, with the effect of relieving the dysmenorrhœa from which she suffered, and inducing conception immediately after the next menstrual period.

Many will doubtless condemn this procedure; but if the instrument is examined, it will be found to act not only as a cervical dilator but also as a uterine drain, which makes it, in my opinion, far less dangerous than a uterine sound, provided gentle manipulation in introducing be adhered to, and the instrument be perfectly clean. Passing the ordinary uterine sound I do not consider dangerous, except in cases of marked stenosis of the cervical canal, and the three forms of flexions, the cause being purely a mechanical one, and very apparent. After the passage of the uterine sound there is, in these cases, a certain amount of sanguineous exudation, which sometimes does not escape at once; in fact, is often retained a number of hours. Retention of this fluid should not be allowed; for this, in my opinion, is where the danger comes in, as the mucous membrane within the uterus is very susceptible, and quickly acted upon. If this exudation be present, the temperature will rise at once from 102° to 104° F. Quinine and other remedies are generally given, instead of dilating the canal and allowing the immediate exit of the fluid, which would lower the temperature at once; whereas, if this is not done, an acute metritis, and perhaps general peritonitis and death, may follow. The glass stem now in use, in many instances, is a valuable instrument; but this, oftener than the sound, is dangerous, and it is simply that it excites more secretion, and does not permit sufficient exit for it. It can very readily be understood that, if the dilator that I have above described be *in situ*, it would be impossible for any of these exudations to accumulate or be retained, for nothing could afford better drainage for the uterine cavity than this instrument does; hence I would advocate its use in any case that needs uterine drainage. It is particularly adapted to any such case as above described. For introduction, the patient can rest either in Sims' position, or on the back, if using a bivalve speculum. The dilator is then put in the grasp of an instrument made especially for this purpose, such as is seen in the accompanying cuts. It is about ten inches long, and consists of two small steel blades, crescentic in shape, slightly curved, and about half an inch in length, which at the end fall together, making it similar to a slightly flexible blunt probe. There is a small space between these two blades, which gradually increases in size for two-eighths of an inch, then grows smaller, and coalesces in a slightly flexible rod which is about an inch long, smooth and round; on this there is a movable ball; the blades are shaped to hold and compress the smaller or inner end of the dilator, and, being movable, can be adjusted to any sized instrument that may be required. The rod now continues on, slightly increased in size, and terminates in



a handle; over the rod there is a spiral spring, about five inches long, with a circular attachment at either end, the one for pressing the spiral spring forward and upward with the finger, the other for holding the outer end of the dilator against the cervix while the introducer is withdrawn. The whole of this instrument should be silver-plated, though it is impossible for it to be soiled by use except on the end that holds the dilator. The introducer is about the size of the average uterine sound, and can also be bent in case there is any unusual deformity of the canal, though I think this will very seldom be found necessary. But to continue with the introduction of the instrument. A tenaculum should then be hooked in the cervix to steady it, and a sound passed to ascertain if there is any obstruction or irregularity of the cervical canal; being satisfied on this point, the dilator can now be introduced in precisely the same way as an ordinary sound. It must be remembered that to obtain a successful result the mucous membrane of the cervix should be uninjured; hence the operator must proceed with the gentlest kind of manipulation.

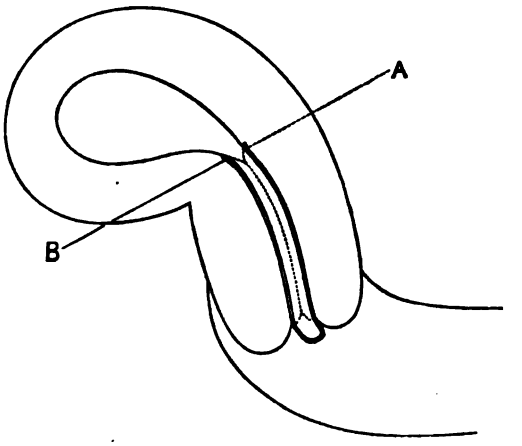
It will be noticed that in withdrawing the introducer the blades of the dilator are allowed to distend gradually, thus causing the patient no pain or discomfort. The protruding part of the dilator fits close to the cervix and does not interfere in the least with the movements of the uterus, nor can it be noticed during copulation. The accompanying cuts will show the dilator while being introduced, and when in place; also cuts of flexions in which these dilators will prove serviceable, as shown by A and B, A indicating point of constriction, and B the dilator, and, further, showing the necessity for instruments of different sizes and shapes.



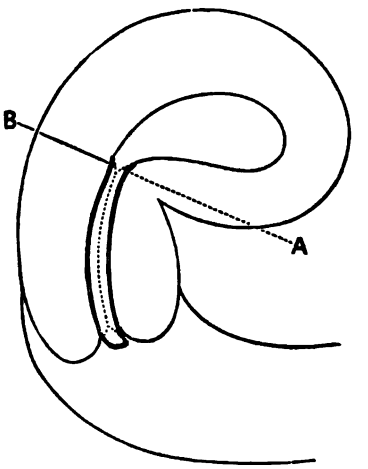
I claim for this instrument that it dilates the cervical canal, making it possible in every instance, after copulation, for the semen to gain admission to the uterine cavity, thus bringing the male and female vital principles together with certainty. It is my belief that conception usually occurs in the tubes; but then, if the spermatozoa gain admission to the uterine cavity, they can without doubt, by the motions peculiar to themselves, quickly reach the required goal.

I do not for a moment believe that sterility may not be due to some change in position of the tubes caused by surrounding inflammations and to previous attacks of peritonitis, or some bands that might constrict the tube itself, and so form a barrier to the ascent of the spermatozoa, and perhaps the descent of the ovum. In the normal state of affairs the large portion of semen is deposited in the vagina, and there undergoes decomposition; a small portion, if the cervical canal be normal, gains admission to the uterine cavity, and a still smaller portion to the Fallopian tubes. Now, if the tubal obstruction does exist, it can very readily be seen that there is a very slight chance of impregnation; for the small amount of semen that does gain entrance into the uterine cavity probably exhausts all its vital force here, or in passing the tubal obstruction. How much greater the chance of impregnation when a large quantity of semen gains admission, as is undoubtedly the case where the dilator is in the canal.

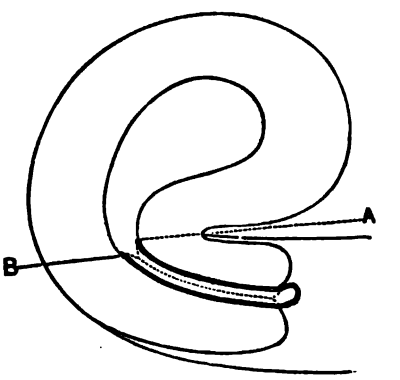
The indications for the use of this instrument are very



clear to my mind, and may be summed up in a few words: Obstruction of every kind in the tubes, whether due to inflammatory masses, old adhesions, or any malposition; also in slight discharge originating in the tube or ovary, a large and congested uterus, or with dilatation of the cavity, metritis or endometritis fungosa, or any growth or distortion involving the cavity of the uterus; flexions of

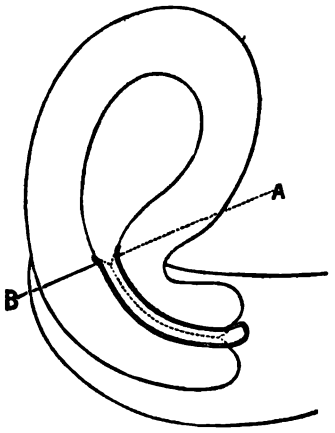


any kind, uncomplicated with stenosis, either involving the neck or body of the uterus; uterine displacements of any description; simple stenosis of the cervical canal or stenosis due to and complicated with anteflexions, lateral flexions, or retroflexions; any irregularity of the cervical canal or any growth or obstruction preventing communica-



tion between the vagina and endometrium; acute, subacute, or chronic cervical catarrh, stenosis of the os itself, or any erosion of the os that would give rise to an irritating discharge, cases of atresia of the vagina, also of profuse vaginal excretions, or when the vaginal secretion is

strongly acid, or contains some principle irritating and perhaps fatal to the spermatozoa; vesico-vaginal fistulæ; also, when there is a small amount of semen, and, lastly, cases that appear to be normal, but, for some reason that



cannot be found or explained, have been sterile. I would direct special attention to the last; for I believe there is a large field for this instrument in this class of patients.

I do not claim that in every instance a good result will be obtained in all the troubles cited, for I believe it better to correct such cases as fistulæ or acid vaginal secretions by some other means, and not rely on the instrument when some better method is afforded.

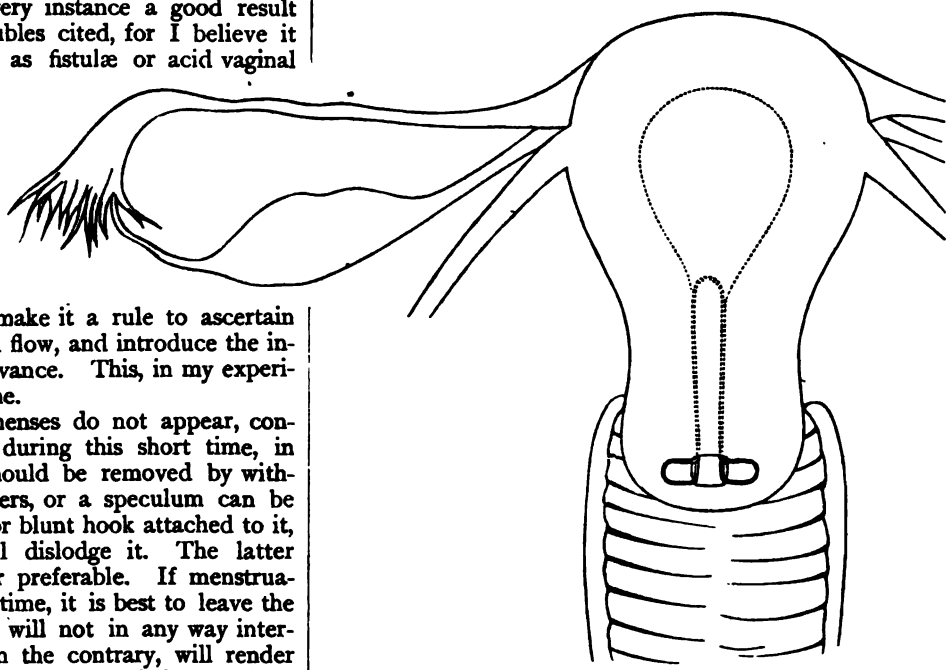
The most likely time for conception to occur is from one to five days after menstruation, though this is not the time I select for the introduction of the dilator. I make it a rule to ascertain the date of the next menstrual flow, and introduce the instrument five or six days in advance. This, in my experience, is the most desirable time.

It often happens that the menses do not appear, conception having taken place during this short time, in which case the instrument should be removed by withdrawing it gently with the fingers, or a speculum can be introduced and a tenaculum or blunt hook attached to it, and very slight traction will dislodge it. The latter method of removal I consider preferable. If menstruation should occur in the meantime, it is best to leave the instrument undisturbed, as it will not in any way interfere with this process, but, on the contrary, will render the flow far less painful than usual. This is especially noticeable to patients who have previously suffered from obstructive dysmenorrhœa; and, further, the instrument will be in position, and all irritation caused by its presence will have subsided, thus leaving everything in the most favorable condition for conception to occur.

The instrument should be left *in situ* for at least from five to eight days following the period. During this time conception should be expected. In case it does not occur previous to the period it should, at the end of this time, be removed, as nothing can be gained by its presence, except in cases where it is not introduced for sterility alone, and of which I will say nothing here. It does not, of course, interfere in any way with the sexual relations; in fact, after introduction the patient is not aware of its presence, unless there is some disproportion in the size of the instrument and canal, or that its shape is not adapted to the particular case in hand. In either instance it will cause some discharge, more or less, depending on the amount of irritation produced. This is a clear indication that the instrument should be removed or changed. Great attention should be given to this point, for it stands to reason that, if the instrument is not adapted to a given canal—in other words, is too large or too small, or not of the right shape—it may make a decided inroad on the tissues, and perhaps cause a profuse discharge, and even sloughing.

If in the vagina, the walls of which are elastic, we are compelled to use different-sized pessaries and specula, how much more important is it, then, to adjust a well-adapted instrument to the unyielding walls of the cervical canal. The ends of the dilator fit closely to the cervix, and the instrument moves only with the uterus and does not in the least restrict uterine or vaginal movement.

There are several advantages connected with this dilator: First, it is self-retaining and non-irritating (when properly adjusted), and, unlike all other instruments for this purpose, it permits perfect drainage from the uterine cavity. So far as my experience with this instrument goes, which extends over a period of four months, during which time it has been used over eighty times, it has been introduced and worn without the slightest danger, causing no discomfort whatever to the patient. It has been used principally at dispensaries, with no special directions except in case of discharge, pain, or rise of temperature, in which case patients were advised to present themselves at once. They are carefully directed as to the position they should assume following copulation, and this can only be determined at the time the instrument is introduced.



I strongly suspect that gynecologists who will use this instrument will be divided into two classes in regard to the results to be obtained with it—those who will use it with intelligence and those who will not. The former class will obtain good results, and, in proportion, laud it, while the latter will have bad results, and therefore be strong in condemnation. In my experience the difficulty has been in the manipulation, and not in the instrument. It is possible that it may be much abused, especially if used unnecessarily or recklessly. No definite rules can be laid down for its employment, what its shape should be, whether straight, or slightly or much curved; neither as to the time it should be introduced nor under what circumstances, and with what directions as to sexual relation position to be assumed by patient, etc. Such points as these can only be determined after examining each individual case.

I believe careful study will give facility in the use of this instrument, and lead to a proper appreciation of its value. I do not wish to be understood as maintaining that all the numerous instances of sterility so frequently met with can be cured by this agency alone. From the experience I have already had I am led to hope that this instrument will prove a valuable factor, and a much more active

means of inducing conception than any other single device now known to the medical profession.

I will only cite the two following cases among many other similar ones that have come under my care for sterility.

CASE I.—Mrs. F——, aged twenty-eight, married seven years, sterile; sharp, anteflexed uterus, and history of dysmenorrhœa. Dilator was introduced ten days before expected menstrual period, which not coming on, the instrument was carefully withdrawn some sixteen days later. Patient is now pregnant about four months, and everything appears normal.

CASE II.—Mrs. V——, thirty-five years of age, married eleven years; position of uterus about normal; some slight bands behind the uterus. Had been under medical observation, off and on, for three years, receiving operations and gradual divulsion of the cervical canal, counter-irritants, and tamponing. First time instrument was used she had her period as usual. It was withdrawn eight days after it, and introduced seven days in advance of the next expected period, which not coming on, the dilator was withdrawn twelve days later. Directions were of course given to avoid sexual relations except near the periods.

Many similar cases have been thus successfully treated, and a number of others with different histories.

There are a number of instances, of course, in which I would advise against the employment of any active measures, among which are cases of contracted or deformed pelvis, where it would be an inhuman act to allow conception to occur. Great care should be exercised to prove that no such obstacle exists, as it might prove a fatal issue.

Finally, it is my belief that, if the tubes and ovaries are not too thoroughly diseased, and a correct diagnosis be made in cases of sterility, and proper treatment carried out, either by the use of this instrument or some other suitable means, a successful issue can invariably be obtained. The result is simply a question of time, perseverance, and careful observation.

This instrument has been used also with marked success in cases of obstructive dysmenorrhœa, in chronic metritis and endo-cervicitis, also as a uterine drain following curetting of the uterus, and as a dilator after trachelorrhaphy or amputation of the cervix to prevent closure of the canal. In cases of pelvic and other abscess, where complete drainage is essential to success, this instrument will be found valuable. It can, of course, be made sufficiently large for any case. In flexures of the uterus I believe there is a large field for it, though I cannot at present give any absolute opinion of this.

39 WEST THIRTY-SECOND STREET, NEW YORK.

THIRST IN INFANTS.—It is a mistake to suppose that because milk is a liquid food it is at the same time a drink which is capable of satisfying the thirst of infants. Although milk appeases hunger, it makes thirst more intense after it has remained some time in the stomach and digestion of it has begun. It is thirst which causes healthy, breast-nourished infants to cry for long periods of time in many instances. There are many cases of indigestion due to weakness or insufficiency of the child's gastric juice, which would be greatly benefited or even cured if the child were allowed an occasional drink of water.—*Medical Classics.*

INOCULATION OF CANCER.—Dr. Hahn, of Berlin, has recently demonstrated the possibility of inoculating cancer, on a woman who was admitted into hospital for advanced recurrent cancer of the left breast (*The Medical Press*). He transplanted to the corresponding site on the right breast three grafts of cancerous skin, and when the patient succumbed, three months later, a microscopical examination of the tissues at the point of inoculation afforded incontrovertible evidence of the presence of cancerous elements.

THE COLD-WATER TREATMENT OF TYPHOID FEVER.

BY SIMON BARUCH, M.D.,

ATTENDING PHYSICIAN TO THE MANHATTAN GENERAL HOSPITAL AND NEW YORK JUVENILE ASYLUM.

THE numerous inquiries, suggestions, and criticisms which have reached the writer, since the publication of his recent paper on the above subject, induce him to add the following:

The chief aim of the paper was to present to the profession a *résumé* of experience from various reliable sources, together with practical and theoretical commentaries, as food for reflection. The variety of sources, the striking character of the results, together with the fact that it was no pet scheme of my own devising that I advocated, will, I trust, induce the profession to ponder well the points brought out. I ask nothing more. That this result is in process of accomplishment is evident from the fact that the paper has been extensively reproduced, and, editorially or otherwise, commented upon.

One correspondent (MEDICAL RECORD, March 16, 1889) fears "that this stupendous array of facts and figures will not carry universal conviction," because "they run too much athwart an easy-going routinism."

The rule to immerse a patient in a bath of 65° F. for fifteen minutes, every three hours, so long as the temperature reaches 103° F., savors of routine. But this is not true; it is simply a general guide for action, and, as will be seen further on in Dr. Brand's letter, is not without difficulty in its application. The temperature of 103° F. is regarded as an index to the intensity of the infective process, whose ravages it is the sole aim of the bath to counteract. Indeed, a lower temperature is, as I have mentioned, indication for the bath, when the heart and nerve-centres are failing, as manifested by a feeble and rapid pulse, tendency to cyanosis, feeble first-sound and apex-beat, or by stupor, subsultus, hiccough, and muttering delirium. I have, in the necessarily brief outline of the methods, distinctly described the modification of the bath for this condition, viz., a warm half bath with cold affusion. Adhering to a routine full bath would, in these cases, seriously enhance the depression, if it did not lead to death. As I have endeavored to emphasize in recent papers on hydrotherapeutics,[1] everything depends on the method; in the application of no remedy is it so important to individualize. The latter testifies to the great therapeutic value of water, and proves that it is a two-edged sword.

It has been objected "that it is a very delicate adjustment of treatment, when a patient is saved or doomed according as it is inaugurated on the fourth or fifth day." This objection, if valid, would apply to much of our therapeutic endeavor. *Obsta principiis* is the first principle of rational therapeutics. Disease has often been likened to a conflagration, the ease of whose subdual is in proportion to the stage at which it is attacked. In the severe types of malarial fever, for example, one day's—yes, one hour's—cinchonization may save the patient's life; its delay may doom him to death or to a long-continued invalidism, from which quinine could no longer rescue him.

The object of the cold-bath treatment of typhoid fever is to render it mild under all circumstances, by preventing complications. This can only be accomplished if it be treated energetically from the beginning. If, as Fraser has shown, among over two thousand cases not one died which came under treatment before the fifth day, it should be our endeavor to approximate this successful practice. But herein lies a difficulty. The diagnosis cannot be positively made at this early date. We may escape from the delirium by treating all cases of fever, whose temper-

---

[1] Dietetic Gazette, April, 1889.

ature range and other symptoms are suspicious, by the cold bath. Harm will surely not ensue. It is well on the inception to resort to cold ablutions with towels (not sponging). Friction aids heat elimination by dilating the cutaneous vessels, and the shock refreshes the nerve-centres (Winternitz). Then the patient grows accustomed to the more energetic bathing, which may be opened with the half bath, combined with gentle chafing, and gradually culminate in the full bath at 65° F.

I may reiterate here that in no case should the stationary bath-tub be used for treating typhoid fever. Cold ablutions with towels are to be preferred to three-hourly removal of the patient, with its attendant excitement, to a bath-tub in which assistance cannot be readily afforded him on account of its accessibility on one side only. A portable bath-tub must be provided and placed near the bed. The surface should be constantly chafed to prevent chilling, and a stimulant should be administered to assist reaction if indicated. With these precautions collapse-like manifestations need not be apprehended. Collapse can only occur from resorting to temperatures below 65°, or from too long immersion; for it has been demonstrated by the best clinical observers that the cold bath is a heart-tonic, if reaction is provided for (Vogl has never seen a case of collapse in fifteen years' experience). "That the alteration in Peyer's glands will not go beyond the stage of infiltration, if treatment is instituted before the 'fateful fifth day,' is another prediction that raises dubious questionings," says Dr. McCarkey (MEDICAL RECORD, March 16th). Fortunately for the patient, but unfortunately for our pathological enlightenment, autopsies are rare in cases treated by the strict cold bath; only two deaths, occurring from other causes in patients treated before the "fateful fifth day," furnish evidence on this point. One case is reported in the *Lyons Médicale*, 1886, No. 14, and another by Brand in 1883; in the former, dying on the twenty-first day in a typical typhoid fever, there was "no loss of substance, old or new, in the intestine; in the latter (on the thirty-first day) "no ulceration, cicatrix, pigmented spot, only fresh infiltration." Moreover, it may be replied that if diarrhœa, meteorisin, hemorrhage, and dry, red tongue are indications of ulceration of the intestinal glands, the absence of these symptoms in the large proportion of cases treated by strict cold bathing must be accepted as evidence of absence of ulceration. Vogl (*Deut. Archiv. f. Kl. Med.*, 1888, No. 61) says: "The diminution of intestinal symptoms is a very evident effect of the cold bath; a few trials will convince and surprise anyone of its success. Among 221 cases there was a daily average of only 0.7 per cent. of diarrhœal stools, while in the cases treated by a combination of baths with medicinal antipyretics the average was 1.9 diarrhœa. Never was it necessary (in 251 cases) to resort to opium, bismuth, etc.; meteorism with tense abdominal walls was observed only in cases received late; it was diminished by the baths. Bloody stools were noted only twice; peritonitis not at all." If inappropriate diet is capable, as we know, of aggravating the intestinal symptoms, and if proper diet is capable of preventing or ameliorating them, why may not the invigorating effect of the cold bath upon the innervation and circulation influence favorably the local processes, which are but the manifestations of the general infection? Just as quietude, cleanliness, ventilation, and proper feeding have, in recent times, rendered typhoid fever more tractable and reduced its mortality, so does the cold bath, by immensely enhancing the "refreshing influence" of these elements of treatment, make the disease more mild, and reduce its mortality. It is well known that the earlier a case is withdrawn from unfavorable hygienic surroundings, the more pronounced will be the effect of the improved conditions; and this holds good of the early application of that greatest of all invigorating measures, the cold bath.

In reply to the objection that poverty would forbid the execution of the rigorous bath treatment, Brand relates a touching instance. He was called to a case in the fourth story of a miserable house in Stettin, a child, six years old, attended by an old, deaf, and crippled grandmother, a weakly but intelligent boy of eleven, and a sister of twelve, the parents being day laborers. There was one room and a dark closet for six persons. The boy declined to have his sister sent to the hospital, and said that he had sent for Brand because he wanted his sister treated by cold water. The child was regularly bathed and nourished, the temperature chart kept by these children; the girl also fell sick, and now the boy nursed both. He became ill with a mild type and bathed himself also, while his sister and brother were nursed by him. "The little hero's name is Franz Witte; he is to-day a printer in the Redé establishment," writes Brand, "and I have kept the histories written by him as a memorial." Brand also relates the histories of cases complicated with heart-disease, pregnancy, whooping-cough, parametritis, pneumonia, and other diseases, which offered no contraindication to the cold-bath treatment. I am satisfied that, ten years ago, I saved the life of young B——, living nine miles from Camden, S. C., by sending him my own bath-tub. Confidence in the method will thus overcome many of the apparent difficulties of this treatment. In conclusion, I am glad to be able to furnish the following translation of a letter just received from Dr. Brand, the originator of the systematic bath treatment:

"I thank you very much for your kind attention. I had already become acquainted with the contents of the article. A gentleman sent me a cutting from the *Philadelphia Record*, containing a tolerably correct review of your essay.

"You were already known to me by a paper you read in 1886 to the New York Academy of Medicine, on the 'Treatment of Typhoid Fever.' It appears that your views have somewhat changed during the past two years—to the advantage of the treatment. You said at that time: 'The heroic treatment has not found favor in our hospitals,' and in another place 'the sudden submergence into a bath of 60° F. may not weaken a German soldier, but it is not so well adapted to an American constitution' [this quotation is in English in the letter]. With reference to the last sentence, you do not seem to have kept in view the fact that not only soldiers, but, also, small children and old people are bathed in water at 60° F., and that the constitution of our babies is certainly not more tender than that of the adult American.

"The five objections to which you refer, and which you believe may be brought against the water treatment, would, if they really occur, which I do not believe, scarcely have any weight. Do we fear chloroform because the patient is nearer death than life, and looks like a corpse? do we fear the knife because it causes blood to flow?

"Sleep is not interrupted by the water treatment, but stupor, which is by it converted into a three-hourly sleep. Then the stupor returns, and must be (the indication demands it) again removed by a new bath. Good sleep should never be disturbed. That the water treatment is not adapted to hospitals, because patients do not enter before the fifth day, is a misunderstanding. Hospitals must only not expect a mortality from 0 to one per cent., which only occurs to those who receive the typhoid cases before the fifth day. Hospitals must be content with a mortality of four to five per cent. (as an average), hence only the third part of mortality which is usual in the expectant treatment (fifteen to twenty per cent.) If a hospital physician thoroughly understands the method, he only loses the peritonitis and hemorrhage cases, of the others only exceptionally one. You will find more of this in the reports which I have the honor to send you. There is only one real objection to the Brand method, and this is urged only by myself, it is the difficulty of learning it thoroughly, and every one must be his own teacher because there is no school where it is taught. Tübingen, Munich, and Lyons are the only places in the world where this is pos-

sible. Added to this is the fact that there is not only a lack of preparation for it, but the teachings of the schools on the expectant method is wrong and misleading for the water treatment. It appears very difficult for some to believe it possible that the fever patient cannot take cold in the bath, especially if he has been perspiring, and that no fluxion to the internal organs can take place, that bronchial catarrh is not increased by it, that pneumonia and intestinal hemorrhages may not occur. Hence unwillingly (or not at all) does he obey the demand that absolutely no change shall be made in the principle of the treatment, viz., to bathe every three hours in water at 60° F. for fifteen minutes; that the bath must not at one time be warmer, at another of shorter duration. In one word, the physician cannot enjoy the same latitude in the water treatment that the expectant method affords him. To this point most men object strenuously. They overcome it (like all English people), and if the result does not correspond with mine, the water treatment is pronounced worthless, when really the observer is worthless. If you desire to learn the subject thoroughly, you would do well to look through the works of Vogl, of Munich, and Tripier and Bouveret, of Lyon, because my writings are now out of print. They correspond tolerably well with the latter, though not entirely."

Progress of Medical Science.

Early Experiments with Nitrous Oxide.—Dr. Richard Ellis sends the following account of the influence of nitrous oxide (copied verbatim from a medical book published in 1806): "When Mr. Humphrey Davy, to whom we are indebted for ascertaining the effects of this wonderful agent, breathed seven quarts of it, muscular motions were produced to a certain extent; sometimes he manifested his pleasure by stamping or laughing. At another time, having breathed nine quarts of the air, he first lost the perception of external things, and a vivid and intense recollection of some former experiments passed through his mind, so that he called out 'What an amazing concatenation of ideas!' When he breathed twenty quarts, a thrilling sensation from the chest to the extremities was almost immediately produced. By degrees the pleasurable sensations were increased; he lost all connection with external things, trains of vivid visable images passed through his mind, and were connected with words, in such a manner, as to produce perceptions perfectly novel. He supposed that he existed in a world of newly connected and newly modified ideas. He theorized and imagined that he made discoveries. Upon waking from this semi-delirious trance, indignation and pride were the first feelings produced, by the sight of persons about him. His emotions were enthusiastic and sublime, and he exclaimed with a loud voice, 'Nothing exists but thoughts! the universe is composed of impressions, ideas, pleasures and pains.' After this he expressed his pleasure by laughing and stamping. Mr. Tobin, having taken two quarts into his lungs, laughed, staggered, threw himself into a variety of theatrical attitudes, traversed the laboratory with a quick step and his mind was elevated to a most sublime height. Mr. Wedgwood had six quarts administered to him, when he threw the bag from him, and kept breathing on furiously with open mouth, and holding his nose with his hand, having no power to take it away, although aware of the ridiculousness of his situation. Mr. George Burnett felt a general swell of sensations, which mounted so fast, that had he not desisted to breathe the gas, he would have fainted from ecstasy. Southey, the poet, breathing the gas, exclaimed, 'The air of the highest possible of all heavens must consist of this gas.' For many years after this, not seeing the experiments of Mr. Davy confirmed by other chemists, Dr. James Woodhouse, professor chemistry—Phil. believed the influence of the imagination caused all the effects ascribed to the nitrous oxide. In the winter of 1806, having prepared a quantity of this gas, extremely pure, from the nitrate of ammoniac, made by the direct combination of the nitric acid and the carbonate of ammoniac, two quarts were administered to Henry Latrobe, who breathed it in a fair manner; in one minute he was affected in a most violent manner; he walked up and down the laboratory with a quick step, elevating one leg after the other, and then suddenly throwing it to the ground; he laughed immoderately and convulsively, the tears rolled down his cheeks in large drops and he frothed at the mouth. I immediately resolved to try the effects of the gas on other persons, in doses of two and four quarts. Mr. —— fainted and recovered in three minutes. Mr. —— looked wild, jumped over a high bench and the effect suddenly ceased. Mr. —— placed his arms a kimbo and surveyed the audience with great contempt. Mr. —— was very much deranged; he ran about the laboratory, bellowed like a mad-bull, and struck at every person near him. Same effect a week after. Mr. —— exclaimed, 'I am in heaven, ye Gods, stars, comets, meteors, Mahomet's a jackass, the Elysian fields are a hell compared with this,' and then fainted. Many others laughed and fainted. I am now convinced the gas produces all the effects ascribed to it by the justly celebrated Mr. Davy, and I am happy in having this opportunity of confirming his experiments. The following letter was received from Professor Silliman of Yale (one of the most noted chemists of his day). 'I have lately given the nitrous oxide a full and fair trial, and the result confirms Mr. Davy's account of this wonderful agent. In my own case after only two inspirations, I felt a momentary loss of distinct thought, then sensations of such pure and vehement delight, that after failing in an attempt to express to my friends by articulate words the pleasure I felt, I demonstrated it by leaping up and down, stamping on the floor, and loud convulsive laughter. One of our gravest citizens was made to caper about like a monkey, with all the extravagant gestures of a tragedian, and the grimaces of a Harlequin. Some effect was produced on all who breathed the gas, and the full effect was manifested in six instances out of eight. Six or eight quarts breathed into and out of a sick boy, will always, I believe, produce the effect.'"

Edinburgh Medical Missionary Society.—At the annual meeting of this Society for 1888 it was reported that 23,711 patients had been treated by the missionaries in the dispensaries of the Society or at the homes of the sick. There were twenty-three students preparing for medical missionary services, and on behalf of these there had been expended for books and instruments about $5,000. The income of the Society is inadequate to meet its expenses, and it is obliged every year to draw upon its capital.

Is Syphilis Ever Cured?—"Syphilis is never cured." Such is the positive dictum of Dr. W. R. Gowers in his recent lectures on "Cerebral Syphilis." Dr. Gowers should come to the United States and learn some of the methods in vogue here; for certainly many cases of syphilis in this country get well. "Syphilis," says one well-known American writer, "is one of the most readily managed and promising of all diseases that affect the human race." Says another writer: "In a large proportion of cases, syphilis will run its course and leave the patient in a healthy condition, even though no special treatment is instituted." Still a third American syphilographer says: "By far the largest majority of cases will pass through the trouble easily and happily to a complete cure." It would appear that either American syphilis is a specially benign article, or the English physician writes from very narrow experience in this affection.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 20, 1889.

MEDICAL NEW YORK A HUNDRED YEARS AGO.

THE Centennial celebration now approaching is turning all thoughts to New York as it was a hundred years ago, and some of the facts regarding the medical profession at that time may be appropriately dwelt upon now. In recent issues of the *Medical Register* of this city, and in his classical paper on "Medical New York One Hundred Years Ago," Dr. John Shrady has collected a number of interesting historical notes regarding the state of physic in New York City during the last century.

The Directory of 1787 contains the names of 21 doctors, 7 druggists, 1 midwife, 1 barber-dentist, and 1 surgeon. Two years later the number of physicians had increased to 37, among whom was Dr. Wright Post; but hardly any other name familiar and prominent to-day was on the list. The New York Medical Society was organized with John Bard, President, and a membership of twenty.

The columns of the newspapers of the day were liberally supplied with advertisements of cures for cancer, consumption, etc., while "Leak's Justly Famous Pills" and "Dr. Walker's Jesuit Drops for the Cure of Venereal Disease," seem to have been popular with our revered ancestors.

A literary event of importance at this time was the publication of an American edition of "Cullen's Materia Medica." The English work cost two guineas and a half, a price thought to be highly exorbitant by the American printer.

Considerable excitement was caused at about this period by the horrid practice of body-snatching. Even the sacred precincts of Trinity churchyard were invaded, and Mr. Livingston offered, as Treasurer of the Corporation, $100 reward for the discovery of the offenders. It was the blacks, however, whose bodies were more often stolen; and finally, for purposes of protection, the colored people bought a private yard in Gold Street. The troubles over this matter finally culminated in the riot of one hundred and one years ago, known as the "Doctors' Mob." The account of it given by Mr. Thomas Jefferson may be interesting.

He wrote to a friend: "A riot has taken place in New York, which I will state to you from an eye-witness. It has long been a practice with the surgeons of that city to steal from the grave bodies recently buried. A citizen had lost his wife; he went the first or second evening after her burial, to pay a visit to her grave. He found that it had been disturbed, and suspected from what quarter. He found means to be admitted to the anatomical lecture of that day, and, on his entering the room, saw the body of his wife, naked and under dissection. He raised the people immediately. The body, in the meantime, was secreted. They entered into and searched the houses of the physicians whom they most suspected, but found nothing. One of them, however, more guilty or more timid than the rest, took asylum in the prison.

"The mob considered this an acknowledgment of guilt. They attacked the prison. The governor ordered militia to protect the culprit and suppress the mob. The militia, thinking the mob had just provocation, refused to turn out. Hereupon the people of more reflection, thinking it more dangerous that even a guilty person should be punished without the form of law, than that he should escape, armed themselves, and went to protect the physician. They were received by the mob with a volley of stones, which wounded several of them. They hereupon fired on the mob, and killed four. By this time they received a reinforcement of other citizens of the militia horse, the appearance of which in the critical moment dispersed the mob. So ended this chapter of history, which I have detailed to you, because it may be represented as a political riot, when politics had nothing to do with it. Mr. Jay and Baron Steuben were both grievously wounded in the head by stones. The former still kept his bed, and the latter his room, when the packet sailed, which was on April 24th."

By the year 1789 New York had already a hospital chartered and organized; but through various misfortunes patients had not yet been admitted. King's University had begun to educate its medical students twenty years before.

Probably the leading physicians of the time were the Drs. Bard, father and son. The former used to drive about the town in a low phæton. He wore a red coat, a cocked hat, and carried a gold-headed cane. His son became still more distinguished, and was the family physician of George Washington while the father of his country lived in New York.

MEDICAL MEN AND THE MANAGEMENT OF MEDICAL COLLEGES AND HOSPITALS.

IN an address recently delivered before the Medical Society of Philadelphia, Dr. Alfred Stillé speaks forcibly of the importance of medical colleges being managed wholly or almost wholly by the faculty, and not by laymen.

He quotes *The Nation* as saying: "No university has anywhere ever become a great influence, or anything but a school for children, which was not wholly or almost wholly in the hands of the faculty or teaching body. The faculty is the university. If you have the right sort of faculty you have a university, though you have only a tent to lecture in. If, on the other hand, you try to make a university out of a board of sagacious business men acting as trustees, and treat the professors as simply 'hired men,' bound to give a college so many hours a week, you may have a very good school for youths, but you will get no enlightening influence or force out of it for the com-

munity at large. Instead of speaking with authority on any of the great themes of the day, the college will be sneered at, as colleges are apt to be in the United States to-day, as the homes of theorists and pedants, whose impudence in differing in opinion from millionnaires merits and is sure to receive severe rebuke."

This principle, so universally admitted to be true for colleges, ought to apply in a great measure also to the management of hospitals. In almost all hospital management, as at present conducted, the physician has practically no voice or representation. In one large hospital in this city the rules even forbid the election of a medical man to the governing board, a rule which is little less than an insult to the medical gentlemen who serve the institution so favorably.

It is quite true that many physicians are poor business men and not fitted for or inclined to executive work. This is not much less true of the generality of laymen. On the other hand, the special knowledge required in looking after the needs of a hospital must be acquired largely by consultation with physicians, who are thus made to contribute their services gratis, not only to the patients but to the wealth and piety which are the only modern requisites for a hospital manager.

THE CONDUCT OF THE SURGEON.

In Vicary's curious old work, "The Anatomie of the Bodie of Man," written in 1548, we find a disquisition on the art of surgery, and the qualifications of the surgeon, which applies not at all badly to the present day. As chief surgeon to St. Bartholomew's Hospital, and one of the patchers up of Henry the VIII.'s syphilitic legs, besides being surgeon to Queen Mary, Edward VI., and Queen Elizabeth, Vicary had excellent opportunity to learn what should constitute a good surgeon.

And it is evident that Mr. Vicary lays much stress upon the natural, moral, and physical qualifications of the man, for he says, phonetically, "Upon this poynt al Authors doo agree that a Chirurgeon should be chosen by his complexion [natural temperament], and that his complexion be very temperate and al his members wel proportioned." It is also insisted that the surgeon "be a good liver and a keeper of the holy commandments of God." [Two things now looked upon as somewhat antagonistic.]

It is agreed by "al Authors that his body be not quaking, and his hands stedfast, his fingers long and smal, and not trembling; and that his left hand be as ready as his right hande, with al his lymmes able to fulfil the good workes of the soule."

To be perfect in his art, Mr. Vicary notes "foure thinges moste specially that every chirurgeon ought to have: The first that he be learned; the seconde, that he be expert; the third, that he be ingenious; the fourth, that he be wel manered."

Experience, learning, ingenuity, and a fine behavior are truly excellent qualities for the surgeon of to-day as well as of three centuries ago.

The learning that Vicary advises is "the principles of Chirurgie and Physicke, natural Philosophy, Grammar, Rhetoricke, and Anatomie."

He must be "ingenious and wittie; for al things belonging to Chirurgie may not be written, or with letters set foorth."

Under the head of manners our author discourses well upon the subject of surgical ethics. The surgeon, he says, "must be no spouse-breaker or drunkard. Likewise a Chirurgeon must take heede that he deceive no man with his vain promises, for to make of a smal matter a great, because he would be counted the more famous." The chirurgeons must not be flatterers, or mockers, or backbiters. They must not be proud or presumptuous, nor covetous or niggardly. They shall give no counsel except when asked, and they must "be privie and secrete as any Confessour of al things that they see or hear in the house of their Pacients." They must be bold in those things whereof they are certain, and cautious in all peril. They should not chide the sick, but be always pleasant and merry. They must not covet any woman "by way of vylanie, and specially in the house of their Pacient"—this special stress being evidently made a slight concession to the dominance of the sexual passion.

The author adds: "He shall not for covetousness attempt to cure incurable diseases, or set a day when cure will be complete."

The surgeon must be gracious and good to the poor, "and of the rich take liberally for bothe," an injunction scrupulously followed by some at the present day.

Surgeons should never praise themselves, "for that redoundeth more to their shame than to their fame;" and a "cunning and skilful chirurgeon neede never vaunt of his doings, for his works will ever get credit enough."

We conclude Mr. Vicary's excellent discourse with his own final and most pertinent injunctions, that the surgeons "despise no other chirurgeon without a great cause; for it is meete that one chirurgeon should love another as Christe loveth us all; and in thus doing they shall increase both in vertue & cunning to the honour of God and worldly fame. To whome he bring us al. Amen!"

The precepts taught at St. Bartholomew's for so long have not grown old, but apply with good force to-day.

News of the Week.

Medical College Commencements.—So far, we have recorded announcements of 25 medical colleges, which have graduated about 1,800 physicians. Further announcements are: Ellsworth Medical College, 9; Keokuk College of Physicians and Surgeons, 39; University of Georgia, 53; Howard University, 10; Iowa College of Physicians and Surgeons, 9; Arkansas State Medical College, 22; Fort Wayne Medical College, 9; Memphis Hospital Medical College, 63; Detroit College of Medicine, 43.

A New Naval Hospital.—Surgeon-General Browne, U. S. N., recently visited Portsmouth, N. H., and selected a site for a new naval hospital, which will be built this summer on Leary's Island. The building will front the inner harbor. It will be a brick structure, three stories high, with accommodations for twenty or twenty-five patients. The upper stories will be devoted to the general service. The new building when completed will cost $35,000.

The Illinois State Medical Society meets at Jacksonville on May 21–23.

SOME RECENT JUDICIAL DECISIONS.—The Supreme Court, General Term, recently handed down decisions to the effect that a doctor may be convicted for practising without a license, though he has been following his profession here for thirty years; that fifteen thousand dollars is too much, and ten thousand enough, damages for the loss of a boy's arm; that a physician's lips are sealed as to information acquired while attending a patient professionally.

THE COMING MEETING OF THE AMERICAN MEDICAL EDITORS' ASSOCIATION.—The meeting of the American Medical Editors' Association will be held at the Casino at Newport, Monday evening, prior to the opening of the American Medical Association. The editor and staff of the *New England Medical Monthly*, together with a few friends, will tender to the Association a steamboat excursion, with plenty of water on board, and at the end of the sail a regular old-style Rhode Island clam-bake.

BEQUEST TO DENVER MEDICAL COLLEGE.—Mr. Jacob Haish, of DeKalb, Illinois, has recently given $15,000 to the medical department of the University of Denver which makes a total of $40,000 that Mr. Haish has given to the University.

THE MEDICAL AND CHIRURGICAL FACULTY of Maryland (State Faculty) will hold its Ninety-first Annual Session April 23d–26th, 1889. Professor William Oster, of Johns Hopkins University, will deliver the Annual Address on "The License to Practice," with special reference to State Boards.

THE MICHIGAN STATE MEDICAL SOCIETY.—The Twenty-fourth Annual Meeting of this Society will be held at Kalamazoo, Mich., May 9 and 10, 1889.

THE SHELBY COUNTY (IND.) SOCIETY celebrated on April 8th its Second Anniversary, by a scientific meeting, a dinner, and the election of officers for the ensuing year. Dr. R. R. Washburn, of Waldron, is President, and Dr. I. W. Inlow, of Cynthia, Secretary.

THE ORGANIZATION OF THE AMERICAN MEDICAL ASSOCIATION for its meeting, June 25th, 26th, 27th, and 28th, is as follows:—*Practice of Medicine, Materia Medica and Physiology:* Dr. F. C. Shattuck, Chairman, Boston, Mass.; Dr. G. A. Fackler, Secretary, Cincinnati, O. *Obstetrics and Diseases of Women:* Dr. W. H. Wathen, Chairman, Louisville, Ky.; Dr. A. B. Carpenter, Secretary, Cleveland, O. *Surgery and Anatomy:* Dr. N. P. Dandridge, Chairman, Cincinnati, O.; Dr. W. O. Roberts, Secretary, Louisville, Ky. *State Medicine:* Dr. J. Berrien Lindsley, Chairman, Nashville, Tenn.; Dr. S. T. Armstrong, Secretary, U. S. M. Hospital Service. *Ophthalmology:* Dr. George E. Frothingham, Chairman, Ann Arbor, Mich.; Dr. G. C. Savage, Secretary, Nashville, Tenn. *Laryngology and Otology:* Dr. W. H. Daly, Chairman, Pittsburg, Pa.; Dr. E. Fletcher Ingals, Secretary, Chicago, Ill. *Diseases of Children:* Dr. J. A. Larrabee, Chairman, Louisville, Ky.; Dr. C. J. Jennings, Secretary, Detroit, Mich. *Oral and Dental Surgery:* Dr. F. H. Rehwinkle, Chairman, Chillicothe, O.; Dr. E. S. Talbot, Secretary, Chicago, Ill. *Medical Jurisprudence:* Dr. James V. Kiernan, Chairman, Dunning, Ill.; Dr. T. B. Evans, Secretary, Baltimore, Md. *Dermatology and Syphilography:* Dr. L. D. Bulkley, Chairman, New York; Dr. W. T. Corlett, Secretary, Cleveland, O.

THE ACADEMY OF MEDICINE, CINCINNATI, O., elected the following officers for the ensuing year: President, Dr. William Judkins; 1st Vice-president, Dr. George W. Ryan; 2d Vice-president, Dr. W. S. Christopher; Recording Secretary, Dr. G. A. Fackler; Corresponding Secretary, Dr. G. W. Withrow.

THE ANNUAL SESSION OF THE MEDICAL ASSOCIATION OF THE STATE OF MISSISSIPPI for the current year was held in the City of Jackson, commencing on April 17th.

THE SOUTH CAROLINA MEDICAL ASSOCIATION will hold its next annual meeting at Charleston, S. C., on Wednesday, April 24, 1889. An address will be delivered by Dr. Robert Battey, of Rome, Ga.

A DINNER TO DR. TRAILL GREEN, OF EASTON, PA.—The Medical Society of Northampton County, in connection with the celebration of the Fortieth Annual Meeting of the Society, propose tendering a complimentary dinner to Dr. Traill Green, of Easton, the founder of the Society.

BEQUESTS TO MEDICAL INSTITUTIONS.—The will of the late Mrs. Turner Sargent, daughter of Dr. Oliver Wendell Holmes, contains, among others, the following public bequests: $5,000 to the Massachusetts General Hospital for a free bed, to be called the "Turner Sargent" bed; $1,000 each to the Children's Hospital and House of the Good Samaritan of Boston; $10,000 to Harvard Medical College, in memory of her father, the income to be applied to the use of the anatomical department, under the direction of the professor of anatomy.

THE LIBRARY OF THE NEW YORK HOSPITAL has recently been enriched by the addition of the library of the late Dr. T. T. Sabine, containing about five hundred bound volumes, besides over two hundred and fifty pamphlets; it has also received about one hundred and fifty volumes from the library of the late Professor J. C. Dalton. While congratulating the Hospital on its valuable accessions, it seems a little unfortunate that so many works should go down below Eighteenth Street and beyond convenient access for nine-tenths of the physicians of the city.

AN OLDER GREEK LETTER MEDICAL SOCIETY.—Dr. John L. Gish, of Jackson, Mich., writes: "In your number of March 16th, you call attention to a Greek letter medical society, the Delta Epsilon Iota, organized by the students of the Yale Medical College. This notice calls me to acknowledge the formation and organization of the second *strictly* Greek letter medical fraternity in the United States, or elsewhere, of which we have any knowledge. We wish for this fraternity as much success, as much personal good and fellow love as has attended our Society, the Nu Sigma Nu—a strictly Greek letter medical fraternity, organized and formed by several members of the Medical Department of the University of Michigan in April, 1881."

A GREAT EPILEPTIC COLONY.—The municipality of Berlin intends to create a new establishment for 700 epileptic patients, capable of being so enlarged as to receive 1,000, at Bissdorf, a village near the city. It is to have a farm and ample grounds attached to it, and is to consist of a central building and many cottages scattered over the grounds, each with a garden around it. The whole will cost about $1,182,500.

THE LOCAL APPLICATION OF ANTIFEBRIN.—Dr. A. H. Neuth writes to the *Lancet* that he has had remarkably good results in the use of antifebrin, externally, as a sedative. His usual plan is to prescribe it with lanoline or vaseline in the proportion of twenty grains to the ounce, combined with other ingredients that seem applicable to special cases. In obstinate irritable ulcers it soothes the pain and subdues the inflammation. In psoriasis, combined with some mercurial preparation, it acts like a charm. He has also tried it in erythema, erysipelas, eczema, herpes, urticaria, and other complaints associated with considerable irritation, and has found it a most useful adjunct to suitable remedies.

DR. JOHN W. WILLIAMS, Surgeon in the United States Army, died at Jackson Barracks, below New Orleans, April 16th. He was a native of Washington, D. C., and was appointed to the Army in 1862. He was medical officer of Merritt's Cavalry Division.

AT A RECENT TRIAL OF TWO APOSTLES OF "FAITH-CURE" in Sioux City, Ia., for practising medicine without a license, the judge instructed the jury to find for the defendants, as it was no crime under the laws of Iowa for a person to pray for an afflicted neighbor.

NOCTURNAL MEDICAL EDUCATION.—Says the *Lancet*: "It is said that no less than from ten to fifteen per cent. of medical students in Dublin pursue their medical studies and attend their prescribed courses of lectures at night. They stick to their business or desk during the day and become medical students at night, with such accommodation as some schools in Dublin provide for them. We cannot think that such a system is one of true medical education, such as the Medical Council contemplates or could recognize. Four years for the medical curriculum is all too little, and it certainly does not mean that students are to divide their time between commerce and medicine. If such a system were pursued in the United States, it would meet with severe criticism from all medical educationists here." Such a system does prevail in the medical and law schools at Washington, D. C.

SIMPLE TREATMENT FOR CORYZA.—Camphor in various forms is frequently recommended for colds in the head, although Dr. George Johnson and others long since indicated the dangers attending the use of concentrated alcoholic solutions. The following method of application is suggested in a Swiss pharmaceutical journal, and certainly has the merit of simplicity: A jug is half-filled with boiling water, into which a teaspoonful of well-powdered camphor is thrown. A funnel-shaped paper cap is then placed on top of the jug, and a hole torn in it just fitting the nose. The camphorated steam is inhaled through the nose for ten or fifteen minutes, the inhalation being repeated, if required, every four or five hours. If the patient resolutely persists with the inhalation, in spite of its unpleasantness, it is said that three repetitions will always effect a cure, however severe the coryza may be.—*Lancet.*

THE ASCENT OF MAN.—In view of the recent assertion that the upright position of man had something to do with the development of disease, the following note from the *Journal of Comparative Medicine* is interesting: "According to Dr. J. B. Sutton, animals are not free from certain diseases thought to be referable in man to his erect position. One-fourth of the female monkeys dying in the London Zoological Gardens have displacement of the uterus, and the same disease occurs in the lioness, tapir, Cape hunting dog, pigmy hog, antelope, etc., and in domesticated mammals. Two cases of inguinal hernia in monkeys are recorded, and the disease is said to be common in horses."

Obituary.

REUBEN SMITH, M.D.,

NEW YORK.

DR. REUBEN SMITH, one of the best known and most popular physicians on the east side of the city, died on April 4th at his home, No. 305 East Eighteenth Street, after a week's illness, from pneumonia. He was born in Pennsylvania in 1833, and graduated at the Philadelphia Medical College in 1856. Then he came to New York and opened an office in West Twenty-second Street, practising there until the outbreak of the Civil War, when he was appointed as Assistant Surgeon in the Navy. He served throughout the war. He continued in the Navy until 1868, serving with much distinction at different times on the U. S. ships-of-war Supply, Chicopee, Marblehead, and John Adams.

Since retiring from the Navy he has lived in East Eighteenth Street, where he built up a practice which was only limited by his physical inability to attend to it. He never recovered from the disabilities which he received in his country's service, and his early death was without doubt caused by exposure in Norfolk and Charlestown harbors.

SAMUEL W. GROSS, M.D.,

PHILADELPHIA, PA

DR. SAMUEL W. GROSS, the well-known surgeon of Philadelphia, died on April 16th, aged fifty-two years. He was a son of the late Professor Samuel D. Gross, and succeeded him in the chair of surgery in Jefferson College. Dr. Gross was born in Cincinnati, February 4, 1837. He was educated at Shelby College, Ky., and studied medicine in the medical department of the University of Louisville and at Jefferson Medical College. He was graduated in March, 1857, and settled in Philadelphia. He soon made headway in his profession, and became an active member of the College of Physicians, Pathological Society, County Medical Society, and of the State Medical Society of Pennsylvania, and was at one time President of the Association of American Medical Colleges. Dr. Gross was the author of several valuable surgical works, and was a frequent contributor to periodical literature. He enjoyed deservedly a reputation for sound learning and great practical skill.

C. J. B. WILLIAMS, M.D.,

LONDON, ENGLAND.

THE death of Dr. C. J. B. Williams took place at Cannes, on March 24th. Dr. Williams was in his eighty-fourth year. His contributions to the subjects of pulmonary disease and physical diagnosis were of the highest importance, and he was at one time a pioneer in the introduction of exacter methods of research. Not long ago, he published a most entertaining volume of memoirs, containing an account of his own work, and of the progress and changes in medical opinion during his long life.

WILLIAM GIRDNER, M.D.,

GREENVILLE, TENN.

DR. WILLIAM GIRDNER, died at his home, near Greenville, Tenn., on the 14th of this month. He had been in the continuous practice of medicine for more than fifty-five years; he did a large practice, and only retired from it a few months ago. He was eighty-one years of age when he died. He was the father of Dr. John H. Girdner of this city.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 4, 1889.

ALFRED L. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

OIL PORTRAIT OF EX-PRESIDENT ABRAHAM JACOBI, M.D.

AN excellent oil portrait of Dr. Loomis's immediate predecessor in office was presented to the Academy by Dr. August Caillé and some of his colleagues. Dr. Caillé, in his presentation address, spoke in terms of admiration for Dr. Jacobi's personal qualities and high scientific attainments, and trusted that he might live to adorn the profession well into the twentieth century.

DR. LOOMIS, in accepting the gift from the Committee in behalf of the Academy, said it was a fitting tribute to Dr. Jacobi's untiring energy and self-sacrificing devotion to the interests of the Academy, as well as to his valuable scientific work.

DR. T. GAILLARD THOMAS read a paper,

ACUTE MANIA AND MELANCHOLIA OR HYPOCHONDRIASIS AS SEQUELÆ OF GYNECOLOGICAL OPERATIONS.

His object was to place on record what he thought must be rather a remarkable experience as to the occurrence of these conditions. Before speaking to the subject he desired to call attention to the fact that he did not announce these peculiar and alarming states as complications or necessarily results of operative procedure, but merely as sequelæ which might or might not be dependent upon them. He further disclaimed the position that operations performed for the relief of diseases peculiar to women were especially liable to these consequences, but, as all the surgery which he performed was limited to those diseases, he must confine his remarks to that field.

The symptoms of mania in these cases were marked by mental exaltation, violent delusions of an emotional nature, rapid and irregular muscular efforts, usually unat tended by disposition to inflict injury upon self or attendant; the eyes were bright and piercing in glance, the tongue red at the edges and furred in the centre, the pulse rapid, the temperature not much elevated, the voice sharp, high-pitched, metallic, the patient talked rapidly and incoherently.

In acute melancholia the patient was less excited, less turbulent, was sad, and more depressed in bearing. She looked gloomy, and often declared her death would occur very soon; at times she became calm, at others she weeped and bemoaned the fact that she was pursued by some nemesis in consequence of some (imaginary) crime.

Dr. Thomas had six cases to relate, out of which four were violent and showed great mental exaltation throughout, while two were melancholic, and after a short time died.

CASE I.—A single woman had, a year before he saw her, noticed an abdominal enlargement which steadily and rapidly increased. During this time she had emaciated much, and when she came under his care was extremely weak and low-spirited, and felt that unless she was relieved very soon she would die of exhaustion. There was a large amount of fluid in the peritoneum, and a tumor occupied the whole of the left side of the abdomen. Although the case was not looked upon as a favorable one, it was determined to operate as the only means of saving life. The patient rallied well after the operation, the pulse kept up to about 100; there was nothing to excite alarm except her extreme nervous depression. She felt certain that she would die. With the exception of this symptom, she appeared to be progressing favorably until the seventh night, when she became more than usually nervous and excitable, and desired to see the priest, who was accordingly sent for. On the eighth day Dr. Thomas saw her and found a great change had come over her during the night. She was wildly maniacal, constantly talked in an incoherent manner, and behaved as a case of puerperal mania. After soothing her for some time he succeeded in getting near enough to feel the pulse, which he found to be 160. She died, in a state of coma, that evening. At the time of this patient's death, eight years ago, he regarded the condition which destroyed life as acute septicæmia, but much experience with septicæmia since then had convinced him that he was in error. This case was by far the most rapid he had ever met, the acute stage being not more than thirty-six or forty hours. An autopsy was not permitted.

CASE II.—Mrs. X—— came under his care on account of severe suffering during the menstrual periods. She was a stout, handsome, healthy-looking woman. Five or six days before the menstrual flow she began to suffer intolerable neuralgic pain in the region of the ovaries. He removed these organs, and she recovered rapidly, but at the end of three weeks a low grade of melancholia developed, and later assumed the form of violent acute mania, with a marked tendency to strike her attendants. She was removed to an insane asylum, returned home at the end of five months, and had remained well since.

CASE III.—A Jewess, aged thirty-six, operated upon for laceration of the perineum. There was nothing unusual until the ninth day, when the sutures were removed. She then became violently maniacal, and it being utterly impossible to control her, a strait-jacket was applied. She raved violently, and after four days fell into a comatose condition and died.

CASE IV.—Multipara, past forty years of age, was operated upon for a badly lacerated cervix uteri. There was nothing unusual until five or six days after the operation, when his assistant told him the patient behaved in a very peculiar manner. On the ninth day she requested a private conversation with Dr. Thomas, at which she confessed a crime committed a few years before. It was told in a manner that he did not doubt it being true until later. She went home for some days, but after two weeks returned to his private hospital, being constantly remorseful because of some supposed crime. She continued this way, growing weaker, and after ten days died, comatose. Incontrollable insomnia was one of the most marked features of this case.

CASE V.—Mrs. C——, aged sixty, was operated upon for a tumor of the breast. Even before the operation she seemed to be a flighty, eccentric person, but after the operation all these symptoms were intensified. She became greatly depressed, was sure she could not live; acute melancholia developed, she cried by the hour, refused to speak, refused all food, had to be sustained by rectal alimentation. She lived about two weeks after the breaking out of the attack, slowly passed into coma, and died. Toward the close of the case the urine became albuminous and presented hyaline casts, but not earlier.

CASE VI.—Operation for cancer of the breast. Before entering his hospital she acted somewhat queer, but mental aberration was not suspected. On the ninth day, after the sutures were removed, she became at times absolutely maniacal. Periods of perfect calm and lucidity of intellect would occur and last for hours. After a time she was allowed to return to her home, with the hope that a change of scene, etc., would prove of benefit, but she had remained violently insane.

There was little literature on this subject. Dr. Ill, of Newark, was first to write on it, and describe some cases. The last two or three years it had been discussed somewhat in Germany, but the entire number of cases on record, including his own, amounted only to twenty-six. In all of his own cases there were distinct prodromal symptoms following the operation, and antedating some days the formal outburst. In none could he discover a hereditary tendency to insanity. It would be noted that four died, one completely recovered, one was still in progress. In all the six excepting one, the urinary secretion was carefully watched and examined, but in none did the kidneys appear to be factors in the mental state. In four

no iodoform was used at all, so that in them iodoform poisoning was not to be considered. In two it was dusted only along the line of cutaneous incision, where absorption would seem almost impossible. Septicæmia was not a factor.

Dr. Thomas propounded the following questions: 1. Were these twenty-six cases of mania and melancholia really due to the operations which immediately antedated them, or did they follow as mere coincident states? 2. Any great mental strain might be followed by mania; was it at all remarkable that in the vast number of gynecological operations performed the last quarter of a century, that twenty-six cases of this malady should have occurred? 3. If the mania which followed operations in the twenty-six cases was the consequence of the operation, how in the future was the tendency to this accident to be avoided? 4. Were the operations in gynecology any more likely than other surgical procedures to disturb the condition of the mind? He would leave the answering of these questions to others.

Dr. J. B. Hunter said he was personally cognizant of several cases; among them were two or three of the more remarkable ones reported by Dr. Thomas. He thought Dr. Thomas was correct if he held the view that gynecological surgery was not more liable to the accident than general surgery. This was evident from a discussion among surgeons at a meeting which he had recently attended. Many there had some cases to relate.

Dr. Hunter thought the cases might be classified as follows: 1. Where the psychosis was due entirely to the operation, whether gynecological or other operation. These cases, he thought, were comparatively few. 2. Cases in which there was a predisposition in the patient to some nervous affection, and in whom the operation served as a torch to light up the disease. 3. Cases in which the patients were already subject to nervous disease, which would have progressed with or without the operation.

He thought Dr. Thomas had not dwelt very much on the time after the operation at which the mental symptoms manifested themselves. In one of his cases, operated upon for an ovarian tumor, the patient went West, and developed mania a year after the operation. The operation might have had some relation to the mania, and it might not.

A fourth class of cases had been alluded to by Dr. Thomas, when he spoke of iodoform poisoning. This class included all cases arising from poisoning, as from iodoform, bichloride of mercury, carbolic acid. One point should be borne in mind, namely, that a very small quantity of iodoform would in some susceptible patients cause acute mania. He thought that ether might develop insanity in patients predisposed to it. Nothing short of incipient insanity should prevent the surgeon from going on to do an operation. Indeed, there were severe nervous affections, as epilepsy, which were sometimes cured by an operation. There was another class of cases which should be mentioned, those in which mental symptoms developed at the menopause, whether this came about naturally, or prematurely by removal of the tubes and ovaries. He thought the cases of nervous or mental affections benefited by gynecological operations outnumbered those brought on by operations.

Dr. Hunter said there might be some relation between the amount of surface exposed in the operation and the mental symptoms. There was greater danger, perhaps, where much surface was exposed, as in operations on the breast or peritoneum. This would especially be expected if the case belonged to the class of iodoform, bichloride, or other form of poisoning, as the drug would be used in larger quantity than where a small surface was exposed.

Dr. Nichols said that the past eleven years, during which he had been President of the Bloomingdale Insane Asylum, they had had but two cases of insanity due to gynecological operations. In one it was stated by the patient's friends that she was operated upon by Dr. Thomas. They said she had suffered from insomnia from childhood; that there was a hereditary tendency to insanity, and she appeared to him to be a person whose mental balance would be easily upset. In this case, and in the other, a fistula in the abdominal wall remained, but caused no material pain or drain on the system. The other patient had been admitted the past month. He was told by her friends that one ovary had been removed. She was suffering from a very grave type of suicidal melancholia. The other patient had paranoia, or primary delusional insanity.

He thought twenty-six cases was a very small part of the entire number of gynecological operations which had been performed, and he had not supposed that such operations were liable to produce any form of insanity, except possibly for the reason that most of those in gynecology were likely to be long contemplated with great doubt by the patient, and because of more severe shock in cases requiring exposure of large surfaces, as of the peritoneum. He had, in fact, been greatly surprised that the long dread of the operation had not caused mental symptoms in many more cases.

Dr. P. F. Mundé had had one case of removal of the ovaries and tubes in which, twenty-four hours after the operation, the patient became so violent that it was necessary to apply a strait-jacket. She recovered. At that time he thought it was a case of septic mania, but he now thought differently. It occurred seven or eight years ago. Iodoform was not used. Recently he had removed an ovarian tumor with a twisted pedicle. The patient was melancholic, and the day after the operation, on being asked a question, pointed to her lips and refused to speak. She did not speak for three or four days. The temperature and pulse remained nearly normal. Iodoform was applied only along the external sutures. Another recent case was that of a patient who, a few hours after operations for complete prolapsus of the uterus, became furiously maniacal, requiring the strait-jacket. The wound healed perfectly. She recovered after having been maniacal a week.

At first he had supposed operations on the ovaries were more likely to be followed by mental disturbance, but he now doubted it. He thought gynecological operations were no more likely to produce mania than were other operations. Long-continued anxiety about the operation would favor mental disturbance subsequently, and prolonged anæsthesia might have something to do with it. He did not believe iodoform had any influence, for he had seen wounds packed with it, yet the patients did not become maniacal.

Dr. William M. Polk said he occupied a position somewhat at variance with that of the other speakers. He thought women were more predisposed to maniacal disturbance after operations, especially operations done upon the genital organs. If he were asked why, he would answer that in his experience women were more emotional, and when one considered the monthly behavior of her genital organs he found it associated with a great many mental disturbances. For this reason he preferred not to operate on women who beforehand showed any abnormal mental action. He had had the misfortune to attend three of these unfortunate people who had developed maniacal symptoms after being operated upon, all of whom died. It was simple mania, and not a condition resulting from absorption of a medicinal substance. The impression produced upon his mind by those cases was one of such dread of possible similar ones that he now refused to operate upon women who showed mental peculiarities or eccentricities. These cases had confirmed him in the opinion that women were more liable to such derangement after operations than were men. During the intervals between menstruation many women showed the clearest judgment, highest degree of business tact, and ability to stand prolonged mental and physical strain; yet during the period of menstrual flow they were utterly incapable of getting along in ordinary domestic affairs,

keeping everything, from cook up, in a state of turmoil, because of inability to control their temper or irritability. It certainly seemed, therefore, that the female sex was more subject to emotional strain than the male, and that fact should be considered before undertaking operations.

Some had thought the mania in these cases was related to the anæsthetic, but that had hardly been proven, since it did not tend to produce the same kind of mania in other subjects. Some thought the perineum in the female was extremely sensitive, and operations upon it were likely to be followed by mania; others that menstruation had to do with the mania. He was prepared to admit that contemplation and dread of the knife a month or six weeks before the operation might tend to disturb the mental balance, but he did not think it would bring about the terrible distress pictured by Dr. Thomas. One of his cases of mania developed after Alexander's operation. An autopsy was made, and septicæmia and central nervous lesion were excluded. The second case was one of supra-pubic hysterectomy. There was no sepsis. This woman had a sister who was a little "queer." The third patient was operated upon for hydro-salpinx, was affected mentally before the operation; this was intensified afterward; a strait-jacket had to be applied; she was fed by the stomach-tube. She died after two weeks.

The more severe the operation, the greater the shock to produce this mental condition; consequently, one should be more careful in choosing subjects for severe operations, especially in women mentally peculiar, or giving a family history of that kind.

Dr. W. Gill Wylie was not prepared yet to express definite ideas on this subject. He certainly was not positive that gynecological operations caused insanity oftener than other operations. But there was one fact in this class of cases which should not be overlooked, namely, that many of the patients operated upon were imperfectly developed. Those who had an imperfectly developed uterus might also have an imperfectly developed brain. He had operated on quite a number of patients who were insane at the time of operating. In one instance the woman had become insane after giving birth to a child. She was considered by different physicians incurable. Dr. Wylie treated her for subinvolution of the uterus and erosion of the cervix. She returned home sane, except during menstruation she showed some of her former symptoms. The birth of another child was followed by insanity. The tubes and ovaries being found diseased, he removed them, and the patient was much benefited in her mental condition, but not entirely cured.

He had had but one case in which acute insanity followed an operation, that being in a patient who had for years suffered from epilepsy of a severe form. She died a raving maniac. He had thought removal of the tubes and ovaries had a tendency to depress patients somewhat, but later observations had shaken that belief.

He thought the abnormal condition of the rectum, perhaps also of the colon, which often existed in gynecological patients, had much to do with producing reflex nervous disorders and mental disturbance.

Dr. Franklin Townsend, of Albany, related his case which had been referred to by Dr. Mundé. The patient was operated upon a few months ago for salpingo-oöphorectomy. There was marked hydremia, as proven by microscopical examination of the blood. After the operation there was nothing to portend evil. The flow which so frequently follows removal of the ovaries came on the fourth day, and with it there was marked mental depression. The wound healed by first intention, the bowels moved regularly, the appetite was good, the pulse, however, rapid prior to and after the operation. It had been noted in these cases that temperature was of less importance than a rapid pulse. The evening of the seventh day the patient was somewhat hysterical, and by midnight was markedly so; the next morning she was melancholic, refused to speak, and would take no nourishment. In the afternoon she became maniacal, and had to be placed in the strait-jacket. She died in the night, in coma, apparently from exhaustion. It seemed to him the illy nourished condition of the brain was one cause for the melancholia; when vaso-motor paralysis set in, there was hyperæmia of the brain and mania.

Dr. L. C. Gray thought that to Dr. Thomas belonged the credit of describing a new genus of insanity. He had described six cases, and mentioned twenty-two others. Of the six, three were a type of mania, three a type of melancholia, but not one of the three of mania was of the types commonly recognized. There was an idiopathic form of acute mania in which the patient became violent, but not uncontrollable; there was an acute form described as *delirium grave*, probably a cerebritis. The six cases which Dr. Thomas had described belonged to the latter class. This would seem to show that there must be some general underlying condition following the gynecological operation which led to all. If there had been a special tendency in the individuals, it seemed to him so many would not have shown a wild form of insanity. In Dr. Thomas's cases the insanity came on a certain period after the operation, and it seemed to be a symptom pertaining to a general disease, either drug poisoning, or microchemical product in the blood, rather than the result of reflex action. It seemed this form of insanity belonged to what had been called post-febrile insanity. Some cases of the latter were of mania, some of melancholia, some mixed, but all the cases of post-febrile insanity so far described had shown great lucidity of the delusions throughout, and a good prognosis. But four of Dr. Thomas's cases had died. There was no such percentage of deaths in ordinary forms of post-febrile insanity, nor in acute mania, nor in ordinary cases of melancholia; there was, however, in *delirium grave*. The only patients with this form who had been cured had taken enormous doses of ergot. He thought that instead of calling the insanity described by Dr. Thomas, mania or melancholia following gynecological operations, it was far better to call it post-operative insanity, which distinguished it from ordinary post-febrile insanity.

The President had had a case in which Dr. Lange had removed the kidney, the patient being perfectly sane until a week or ten days after the operation, when she developed most acute mania. But she recovered, and was then well.

Dr. Thomas said he had little to add in closing the discussion. He would refer to some points which had been brought up, although they were hardly relevant to the subject. If iodoform possessed the disadvantage of ever producing such grave results as had been described during the evening, it seemed to him that the advantages which pertained to it hardly warranted its use. He was in the habit of sprinkling a little iodoform along the line of sutures which closely coaptated the edges of the external abdominal wound in laparotomy, yet he was not prepared to deny Dr. Hunter's position, that even under those circumstances the iodoform might cause poisoning. He had had some cases of insanity lasting three or four days, due to iodoform poisoning, but had not mentioned them in the paper.

With regard to ether, he did not believe, after a very large experience with it, that in his hands it had ever produced insanity. But he would wander from the subject long enough to say that he had seen such bad results from ether, in the way of prolonged vomiting and general discomfort, that he was strongly inclined to believe American surgeons should follow the example of their European brethren, and use chloroform instead of ether in laparotomies.

It would seem that the cases under discussion were by no means as rare as a reference to the literature would indicate. At this discussion twelve additional cases had been recorded, making thirty-eight. One was his own, mentioned by Dr. Nichols, which he had then for the first time heard of. Dr. Nichols's remark on the evil influence of anticipating the operation had interested him very

much. It seemed to him a wonder that more women with, for instance, tumors of the breast, in going from doctor to doctor, and getting conflicting opinions, did not become crazy. For that reason he had taught students always to remove tumors of the breast, of whatever nature and of whatever size. In writing his paper he said he had gone according to no author, but simply tried to give a word photograph of his own cases. He might say that his own mind was not made up. He hoped the paper would lead to the report of other cases, and that others might be able to answer the questions with which he had closed his paper.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 13, 1889.

WM. P. NORTHRUP, M.D., PRESIDENT, IN THE CHAIR.

DR. JOHN S. ELY presented the

REPORT OF THE COMMITTEE ON MICROSCOPY

on the specimen referred to the committee by Dr. Boldt on January 23d. The tumor presented the structure characteristic of the papillary form of cyst adenoma of the ovary.

DR. FREDERICK S. SELLEW presented a specimen showing

CROUPOUS COLITIS,

occurring in a child aged three and one-half years, who was suffering from pharyngeal diphtheria. The general condition of the child was poor, and she was suffering with whooping-cough when taken with diphtheria.

The membrane covered the surface of the tonsils and pharynx. There was no dyspnœa. The coughing was severe, and an extensive double pneumonia developed a few days before death, and was the cause of death. The child lived about ten days after the onset of the diphtheria, and during a greater portion of this time there was diarrhœa, more or less profuse, but there was no pain, no blood, and no tenesmus.

Autopsy.—The child was poorly nourished and emaciated. The tonsils were enlarged with dilated crypts containing grayish mucus and granular matter. Pseudo-membrane was present on the surface of the tonsils and on the pharynx. The larynx and trachea were normal. There was broncho-pneumonia at the base of both lungs posteriorly, and emphysema anteriorly. The bronchial glands were enlarged, but not cheesy. The stomach and small intestine were normal. To the mucous membrane of the colon, from the anus to the cæcum, there was adhering a flocculent pseudo-membrane, gradually decreasing in quantity from below upward. A croupous inflammation of entire colon existed. Sections of the intestines were examined microscopically by Dr. Northrup, and found to present the usual lesion of croupous inflammation. The spleen, kidneys, and liver were normal.

This case was of interest, Dr. Sellew said, on account of the infrequency of croupous inflammation of the intestines. Dr. Northrup had found the condition but once in over 1,500 autopsies. He had never found it occurring in the small intestines. Weissenfels and Freund have collected records of 103 cases, and in but four of these was the inflammation confined to the small intestine only. In a recent number of the *Medical News*, Dr. B. K. Rachford, of Cincinnati, explains the infrequency of intestinal diphtheria by the theory that the diphtheritic germ is dependent, to a great degree, upon oxygen for its existence. He believes that the presence of the diphtheritic exudate in the intestine is dependent upon some pathological condition of the intestinal tract which would furnish oxygen, either in the free state or in some unstable combination, which could be utilized by the germ for its growth. Such an unstable compound exists in the oxyhæmoglobin of the blood—the congested and eroded mucous membrane being the pathological condition which would bring the germ in contact with this body, from which it would derive its oxygen.

DR. L. EMMET HOLT asked whether it were necessary to regard the colitis as a diphtheritic affection. Might there not be a diphtheria of the larynx and pharynx with, at the same time, a non-specific croupous colitis, occurring coincidently but independently of the former?

THE PRESIDENT said that in this case the local lesions in the pharynx, larynx, and colon resembled each other very closely, and though he was not prepared to assert positively that they were identical, yet he believed that they would prove so to be. He had seen a diphtheritic membrane in the stomach, but had never seen but one other instance of croupous colitis. He had had two cases of colitis occurring at the same time, both of which he supposed to be membranous; one of them, however, turned out to be a simple catarrhal inflammation.

DR. LOCKWOOD asked whether any bichloride of mercury had been used, either locally or internally, in the treatment of this case.

THE PRESIDENT replied that it had not. The throat symptoms, indeed, had been not at all pronounced. If it were true that the lesions of diphtheria were due to the presence of an aërobic micro-organism, the occurrence of intestinal diphtheria might be explained by the entrance of the microbe through the anus, the lesions in such a case being most marked in the parts nearest the anus, and decreasing gradually in proportion to the distance from this point.

DR. R. G. FREEMAN presented a number of gross and microscopical specimens of

ECHINOCOCCUS CYSTS OF THE LIVER,

removed from the body of a Sicilian woman, forty-four years of age, resident three years in the United States, who died at Roosevelt Hospital, last January, with symptoms of cardiac and nephritic disease.

Autopsy.—There were evidences of pneumonia, heart disease, mitral stenosis, congested spleen, chronic diffuse nephritis, and chronic gastritis. The liver was cirrhotic, and in it were two communicating spheroidal cysts. These cysts were close to the base of the gall-bladder, and at one point the larger cyst was separated from the anterior surface of the liver only by a connective-tissue membrane which presented the appearance of a cicatricial depression. The smaller one was more deeply seated. The diameter of the larger cyst was six centimetres; of the smaller, four and one-half centimetres. They were filled with a pultaceous yellow material, which on gross examination showed larger and smaller translucent masses scattered through it. The translucent masses proved, on microscopic examination, to be the characteristic lamellated echinococcus cyst membrane. On examining the yellow material a few hooklets were found. There was much granular matter, some fat-globules, yellow and red pigmented particles, cholesterin crystals, and lime salts. The translucent masses were made up of two distinct sorts of membrane, both, however, exhibiting the characteristic lamellated structure: 1, pieces of thick membrane consisting of several layers, that on one surface being white, the other yellow; 2, complete daughter cysts. The thick pieces of membrane the speaker took to be portions of the mother-bladder; some pieces presented both surfaces plain, but in others there were numerous projections from the white surface which had the appearance of brood capsules. They were translucent, and conical in shape, and a thicker streak passed from the apex to the middle of the base. On microscopic examination they appeared to be an outgrowth from the lamellated layer of the membrane, the lamellæ curving out as they reached this point; they contained no cavity; the darker streak through the middle consisted of lime salts. These, then, if they were rudimentary brood capsules, were sterile and had undergone calcareous degeneration. Just such a structure as this, Dr. Freeman said, he had been unable to find described or illustrated, although sterile cysts are

mentioned. The daughter cysts varied in diameter from fifty millimetres to four centimetres. Seventy-five daughter cysts were isolated, this being probably about two-thirds of the whole number present. Some of those examined were sterile; others contained scolices and hooklets. Some contained granddaughter cysts, and in one there was a granddaughter cyst which contained three great-granddaughter cysts. The scolices were found in all stages of degeneration, in the later stages nothing remaining but a pile of lime corpuscles and hooklets. Lining the cyst cavity outside of all was a dense connective-tissue membrane.

The cyst contents were preserved in a saturated aqueous solution of chloroform on the suggestion of Dr. Prudden. This chloroform water had proved a very good preserving fluid, no organism having grown in it, nor had it had any distorting influence on the specimens.

The speaker thought the specimens worthy of presentation, first on account of the very complete exhibition of the life-history of an echinococcus cyst which they afforded, and secondly on account of these peculiar papillary outgrowths.

The specimens presented were: 1, spleen; 2, liver with connective-tissue membrane; 3, membrane with papilla fresh; 4, membrane with papilla hardened, cut, and stained; 5, a cyst hardened, cut, and stained; 6, fresh cysts showing contents.

Dr. H. P. Loomis presented

A LARYNX AND THREE LARGE PIECES OF MEAT,

illustrating one of the more rare causes of sudden death. A man, who was intoxicated, entered a restaurant, and began to eat, but suddenly choked and fell over dead. At the autopsy, made by Deputy Coroner Jenkins, three large pieces of meat were found in the throat, one of them completely occluding the glottis. In the records of the coroner's office are twenty-seven cases of sudden death from a foreign body in the larynx, in two only of which was food the occluding body.

Dr. George R. Lockwood presented two

URIC ACID CALCULI,

which had been passed by a gentleman, forty-four years of age, of good family and personal history. The details of his illness have been previously given (Medical Record, May 24, 1888) in a communication read before the Section in Practice of the New York Academy of Medicine. Briefly they are these: In 1872 the patient had an attack of renal colic on the right side, which passed away, leaving a sense of dull pain and soreness along the course of the ureter for one year. He had no return of the trouble until 1884, when he was taken with pain in the left side, followed by sharp uræmic convulsions and stupor. Recovered at the end of five days, convalescence being established by free diuresis. How much urine passed during this attack was not known. Recovered and remained well till December 27, 1887, though the urine always contained uric acid crystals. On the latter date he was suddenly seized with pain in the left side, and developed convulsions and stupor, the uræmic attack lasting only for several hours. During the first day he passed 12 ounces of urine, containing 46 grains of urea; second day, 18 ounces of urine, with 142 grains of urea; third day, 4½ ounces, with 35 grains of urea; fourth day, 4½ ounces, with 39½ grains of urea; fifth day, 4¾ ounces, with 48½ grains of urea; sixth day, 4¼ ounces, with 31 grains of urea. During this time a slight drowsiness was his only uræmic symptom. No tumor could be detected in the abdomen. On the seventh day he began to make water in large quantities, passing in twenty-four hours 299 ounces, or 18¾ pints, containing 2,401 grains of urea, and during next two days 68 ounces and 88 ounces, respectively. Then he had another attack of renal colic lasting for four hours, and followed by a diuresis of 188 ounces. Three weeks afterward he passed these two uric acid calculi. From this time on his urine became normal. He remained a comparatively well man until, toward the close of September, 1888, he was suddenly seized with convulsions, became comatose, and died.

Autopsy.—The following is the record of the autopsy, which was made by Dr. Ferguson: "Inspection, no œdema; peritoneum normal; pleura, old adhesions both sides; heart normal in size, valves competent, muscular tissue contains small amount of fat; lungs hyperæmic and moderately œdematous in most dependent parts; spleen bound by tough fibrous adhesions to neighboring parts, normal in size, capsule thickened.

"Left kidney is large and lobulated, surface smooth, capsule not adherent. The entire organ swollen and congested. Markings not distinct. Cortex unusually thick. There are small calculi embedded in the substance of the organ, in both the medulla and cortex. Ureter is normal. Microscopic examination shows considerable fibrous tissue in excess of normal, but the most prominent changes are in the parenchyma. Many of the Malpighian tufts are converted into fibrous tissue, many of them converted into fat. The tubules of both the cortex and pyramid, but especially of the cortex, are far advanced in fatty degeneration. Many of these tubes, not yet in the state of fatty degeneration, show their epithelium to be very granular. There are numerous masses of urates in the cortex and pyramids which require the microscope to bring them into view. The straight tubes contain both granular and hyaline casts.

"The location of the right kidney is occupied by a cyst, which is the pelvis of the kidney, limited by a thin rind of cortex less than one-eighth inch in thickness. At a distance of less than one inch from the pelvis the ureter is completely blocked by a calculus one-half by one-fourth inch in size. The ureter below the obstruction is thickened, its lumen small, the mucous lining cicatricial. The microscope can hardly distinguish a trace of kidney-tissue in the thin rind of cortex which makes up the wall of the greatly dilated pelvis, which has a capacity of four and one-half ounces. Liver large and fatty; stomach and pancreas normal; adrenals, cortices fatty, the fat being distributed in circumscribed masses which stand out in marked contrast to the healthy portion of the organ; bladder, mucous membrane lined by fine calculi, otherwise normal; brain, convolutions over cortex slightly atrophied, brain moderately congested."

There are four points of interest, Dr. Lockwood said, about the case:

"1. Anuria following impaction of a renal calculus, if lasting more than a few hours, signifies destruction of the kidney. The other kidney may be congenitally absent, but, as a rule, it is atrophied by occlusion of its ureter by a previously impacted calculus. We cannot understand a simple inhibitory reflex lasting so long.

"2. Anuria induced in this way is, as a rule, accompanied by slight uræmic symptoms. This is of importance in differentiating obstructive from non-obstructive anuria.

"3. The case throws light upon the origin of hydro nephrosis. Many of the text-books make the assertion that a hydro-nephrosis is due to a sudden and complete stoppage of the ureter: The kidney is secreting urine, the ureter becomes blocked, the urine still continuing to be secreted, dilates the pelvis of the kidney. That this statement is erroneous I think can be proved by the following facts: *a.* When the ureter is submitted to a back pressure of 2.4 inches of mercury this pressure equalizes the blood-pressure in the Malpighian tuft and further secretion is stopped. This pressure is exerted in a healthy kidney by ʒ ij.–iv. of urine. *b.* The pelvis and ureter are not to be distended easily. The ureter will stand a pressure of five feet of mercury. Only one-half ounce of fluid can be injected into the cut ureter and pelvis, any extra force used only drives the surplus out through the renal vein. *c.* As regards autopsies, this case is the only one to my knowledge in which an autopsy has been made after the dislodgement of a calculus that had produced such an anuria. It is valuable, then, for this. The left pelvis and ureter were normal. A num-

ber of autopsies have been recorded where a calculus remained impacted. In these the kidney was atrophied, and the pelvis contained only an ounce or so of fluid.

"4. The diuresis, then, must have been due (*a*) to the diuretic effects of retained urea; (*b*) to a vaso motor dilatation of the renal vessels, following the withdrawal of back pressure when the calculus became dislodged, without compensating vaso-motor dilatation elsewhere."

DR. JOHN S. ELY said that in some cases of hydronephrosis reported by Morris there was a valve-like arrangement causing not a total but a partial occlusion of the ureter, and existing for a long period of time. The condition has also been found in other cases of partial occlusion such as would result from the impaction of a mulberry calculus.

(To be continued.)

Correspondence.

ACUTE MANIA AFTER OPERATIONS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the discussion that followed the reading at the Academy, on the evening of April 4th, of Dr. Thomas' paper on "Acute Mania and Hypochondriasis after Gynecological Operations," it is very remarkable that no one pointed out the identity of the cases described with those which have long been known as cases of "traumatic delirium." This affection was first described by Dupuytren under the name of "délire nerveux,"[1] was accepted as an idiopathic nervous delirium by Nélaton, in 1844,[2] and distinguished from the delirium tremens it so greatly resembles by Follin and Duplay, in 1874.[3] During the last twenty years, however, French surgeons have tended to identify "traumatic nervous delirium" with true delirium tremens, or, at least, to affirm that it only occurs in persons habituated to alcoholism before the occurrence of the wound or the operation; that it has, therefore, much the same pathological significance as the excessive delirium in the pneumonia of drunkards, and like it demands treatment by alcohol and opium. I have heard the late French surgeon Gosselin insist on this view in his clinical lectures at La Charité. The identity of the traumatic delirium with delirium tremens was formally advocated in a celebrated essay by Rose,[4] incorporated in Billroth and Luecke's "Surgery." Rose proposes to call the delirium observed after operations in persons habituated to alcohol "chronic delirium tremens," because it belongs, not to an acute alcoholic debauch, but, on the contrary, to a period of enforced abstinence from liquor in a person whose nervous system has become depraved by continued alcoholic excess, and is therefore unable to bear either shock, loss of blood, or suppuration.[5] Koenig, writing in the same sense, entirely accepts the doctrine of the identity of traumatic delirium and delirium tremens.[6] He claims that the liability to at least some degree of delirium may be incurred not only by habitual drunkards, but by men who had merely been in the habit of taking an ordinary amount of beer or wine without ever becoming intoxicated.[7] On the other hand, Dr. William Hunt, in the "International Cyclopædia for Surgery," admits the existence of traumatic delirium as distinct from the delirium tremens which still more frequently complicates wounds and operations.[1] To the non-alcoholic form of delirium many causes are attributed, especially anything which affects the quality or quantity of the blood. Hence the most prominent cause of afebrile traumatic delirium is hemorrhage; of febrile delirium, septicæmia. An interesting form of operative delirium has been observed after one especial operation—cataract extraction—upon old people, all over sixty.[2] Sichel, as quoted by Schmidt Rimpler, has seen seven or eight cases whose only cause seemed to have been the closure of the eyelids after the operation. Such patients are, so to say, "dépaysés"—they do not know where they are—they get up to go home. Their speech becomes incoherent, they wander about their room, tear off their bandages, and insult their attendants. They are free from fever, and, apart from the delirium, exhibit no trace of cerebral congestion or inflammation.[3]

Several similar cases are quoted by Schmidt Rimpler from other authors.[4] The writer observes that on the whole this delirium of the "dark room" belongs to the delirium nervosum of Dupuytren. He will not admit, with Rose, that all cases of traumatic delirium are to be referred to the delirium tremens potatorum, or to febrile, or to inanition delirium.[5] The special cause of excitation after the cataract operation, where the effect of hemorrhage and of pain must both be excluded, is the suddenly complete privation of sight by means of the bandage. The brain is thus deprived of the regulating, even inhibitory influence, of the sense of vision, and abandoned to its easily disordered spontaneous impulses.[6]

Without pursuing the subject further, it is evident that the cases described by Dr. Thomas are neither peculiar to women nor to gynecological operations, nor do they, however interesting as additional clinical data, represent any new class in medicine. They belong to a class of which some forms were formally described by Dupuytren in 1839, or were observed in his clinic in 1827, and which have since claimed a descriptive chapter in all systematic treatises on general surgery. The interesting questions suggested by these cases are: 1. Whether the delirium is at all, or mainly to be, attributed to moral causes—preoccupation, apprehension, hysterical excitability? 2. Whether, when septicæmia can be excluded, the delirium must necessarily be attributed to avowed or concealed habits of alcoholism? 3. What organic substratum existed for the delirium? a question particularly urgent in regard to the fatal cases.

Of the seven cases reported by Hélis from Dupuytren's clinic,[7] observed between 1812 and 1817, five recovered and two died. But both the deaths seemed to result only indirectly from the delirium, which led the patient in the first case (strangulated hernia) to tear his intestines until he succumbed to an acute peritonitis; while in the second case (operation for popliteal aneurism) the delirium, which broke out on the fifth day, subsided, but the patient died on the fortieth day, after repeated hemorrhages.

Of the other cases the first was operated for sarcocele. The patient, who had been much tormented by fear of hemorrhage, began, on the day after the operation, to be greatly agitated; complained of pains in limbs and chest, and then fell into raving delirium. The eyes were brilliant, the pupils motionless, the respiration accelerated, the face covered with sweat, the pulse remaining calm and regular in the midst of the disturbance. The delir-

[7] One case from the wards of M. Pelletan.

ium was rapidly dissipated by an enema with six drops of laudanum.

Such a transitory affection, so easily cured, in a person predisposed to anxiety about his operation, justly deserves the title of "nervous delirium."

The second case was very similar. The operation, a dislocation of the femur; the patient much frightened by the apparatus employed for reduction, and unable to believe that he was so soon cured; the delirium, again with the cool skin and quiet pulse, occurred on the evening of the same day, but was arrested by an enema with ten drops of laudanum.

In the third case the patient had a fractured rib; the delirium began on the third day after the accident, and was accompanied by great bodily agitation, so that the muscles were in a state of continual tension. Venesection gave no relief. Two successive enemata with ten or twenty drops of laudanum equally failed; but a third, with forty drops, was perfectly successful. The patient, however, had contracted a pleuro-pneumonia during his delirium, from which he only imperfectly recovered.

In the fourth case the patient, while intoxicated, had attempted suicide by cutting his throat. On the second day after the wound was dressed delirium occurred, violent enough to necessitate a strait-jacket. The patient was at first calmed by small doses of laudanum, but from the local irritation the wound assumed a morbid appearance, and on the seventh day the delirium reappeared. It was, however, again treated successfully, and the patient left the hospital cured on the fiftieth day. In this case two alleged causes of traumatic delirium coincide—moral instability preceding the accidents; and alcoholism, not, however, evidently chronic.

The fifth case resembles the last, except in the sex of the patient—who was a woman—and in the absence of alcoholic antecedents. Suspected of theft, this patient had tried in her despair to cut her own throat. She was seized with a violent delirium which lasted ten days, without fever or inflammatory symptoms. The delirium was cured by anodynes, but the wound did not cicatrize until the fortieth day.

Upon these cases M. Hélis makes the following reflections:

"Nervous, pusillanimous individuals, those whose brain had been previously agitated by sudden resolutions, are the most exposed to this delirium; thus it is very frequent after attempts at suicide, so much so that some persons have pretended it was peculiar to them. Athletic individuals are not exempt. It has not been observed among children, and women are much less liable to it than men; probably because their courage is usually more tranquil, more deliberate, for the operations to which they are about to submit."[1]

Hunt, on the contrary, states that children are particularly liable to this delirium, but he gives no proof of the assertion, which seems improbable.[2] Nélaton[3] quotes from Dupuytren the following description, which he indorses as true to nature, without adding anything of his own:

"If, the evening, the next day, or the second day after a fracture, dislocation, attempt at suicide, or any operation, the patient begins to talk with an unnatural gayety; if he speaks much, if his eyes be animated, his phrases abrupt, his movements jerky or involuntary; if he affect a courage and a resolution henceforth superfluous, be on your guard. Soon will be manifested a singular confusion of ideas in regard to persons, places, and things; the patient, a prey to insomnia, is usually dominated by some fixed idea; he is abandoned to a continual jactitation. The upper parts of his body are bathed in sweat; his eyes become brilliant, injected; the face animated, crimson; and with an extraordinary loquacity he shouts out menacing words and frightful vociferations. He becomes insensible to pain, and tears his wounds. . . . But, in spite of the apparent gravity of the symptoms, the pulse is calm and tranquil, and there is no fever. The bowels and kidneys function well; but there is complete anorexia, and, after two, four, or five days, the affection may terminate in death, though much more frequently by recovery."[1] To this description Nélaton adds the remark that, in the few cases where an autopsy had been obtained, no alteration had been found of brain, cord, or, indeed, of any organ. In 1874 Follin and Duplay repeated the same remark.

The diagnosis is made with delirium tremens, with which the nervous delirium is admitted to have much analogy. But, besides the fact that the former follows upon alcoholic excesses—the latter only upon a wound or operation—the traumatic delirium does not present the same uncertainty of voice, trembling of lips, complete loss of equilibrium.

Thus the earlier observers took no account of the possibility upon which Rose laid such stress, of an outbreak of delirium tremens as a manifestation of chronic alcoholism; as a consequence of nervous shock and hemorrhage, coinciding with a temporary privation of the daily dose of alcohol. According to Koenig, the latter circumstance may itself suffice, without traumatism, to cause an outbreak of delirium tremens in a chronic alcoholic. The testimony of other surgeons, and the clinical histories themselves, both contradict the absolute exclusiveness of the Rose theory, however frequently this may be justified. Among the six cases related in Dr. Thomas' paper, all women, and only one among them a public hospital case, the theory of alcoholism would seem highly improbable, though perhaps not absolutely impossible. Verneuil has called such cases "internal septicæmia;"[2] but of a septic process there is really no proof in at least many cases, though undoubtedly the records of cases antedating the era of antiseptic surgery probably include as cases of nervous delirium many where the cerebral excitement was simply an expression of blood-poisoning.

The most comprehensive statement of the matter seems to be that, when the resistance of the brain has been seriously lowered by one or more of several conditions, the conditions incident to a surgical operation are sufficient to throw it into a state of exhaustion. This state is manifested first by maniacal excitement, which may either subside or pass into coma. In the latter case death is usually inevitable.

The most frequent antecedent predisposing cause seems to be, unquestionably, chronic alcoholism; and Rose has had forty severe cases where he believes this etiological factor to have been proved. But after this comes hereditary predisposition to insanity (neurotic constitutions), powerful emotions, depressed nutrition, especially if pushed to inanition; finally, old age. The second of these non-alcoholic predisposing causes seems to have existed in two of Dr. Thomas' cases, both of whom were noted as "eccentric" before the operation. The operative conditions which may exhaust a thus predisposed brain are: 1. Pain, now eliminated during the operation, but which in Dupuytren's time must have been a terrible factor, and which may still be influential when existing after the operation. 2. Hemorrhage. This, again, is to-day largely eliminated, and is, as well known, often most trifling even in the capital operations of laparotomy. On the other hand, it may be quite profuse in the minor operations on the cervix and perineum. One of Dr. Thomas' six cases was a perineorrhaphy. There remains, 3, a condition which I have never seen mentioned but which I venture to suggest as one which must almost necessarily occur in abdominal, possibly also in uterine and perineal operations—I mean, dilatation of the blood-vessels of the abdomen from reflex inhibition of the splanchnic nerve. It is well known to physiologists that section of the splanchnic nerve is followed by such a dilatation of the abdominal blood-vessels as to greatly

[1] Loc. cit., p. 435. [2] Loc. cit., p. 385. [3] Loc. cit., p. 140.

[2] Quoted by Rose, loc. cit., p. 110.]

lower the tension and increase the rapidity of the radial pulse. In the cases cited by Dr. Thomas, contrary to the observations of earlier writers, the pulse is said to have been rapid; the tension is not described. The lowering of the tension, and consequent compressible amplitude of the pulse regularly occurs in the forming stage of general peritonitis.[1] By the paralytic dilatation of the abdominal blood-vessels it is possible, in animals at least, to withdraw so much blood into the abdominal circulation that the animal may be said to "bleed into his own veins." The circulation of the cerebro-spinal axis is correlatively endangered, and its nutrition impaired as by hemorrhage.

It is here suggested that this condition may therefore suffice to temporarily exhaust a predisposed brain, as a hemorrhage could admittedly do if it had taken place.

The case quoted by Dr. Loomis, of a three weeks' mania after extirpation of a kidney, with the necessary profound traumatism of the renal plexus, and hence shock to the splanchnic fibres entering it, would admirably illustrate this view.

In accordance with it, the impairment to the nutrition of the brain, though sufficient to cause severe functional disturbance, might nevertheless be transitory and easily overcome by opium. Or, on the other hand, beginning as in true delirium tremens with such purely functional disturbance, it might, as in an unquestioned case of that affection, proceed to complete nutritive exhaustion and arrest not only the intellectual functions, but the vital functions of the medulla in regard to the heart and respiration. Hence the terminal symptoms of stupor and coma, followed by death.

Delirium tremens potatorum may end fatally without gross lesion of the brain, unless, indeed, this has already been produced by chronic alcoholism; or, at the most, with passive congestion and increased serosity in the ventricles and nerve-tissue. Even the non-traumatic and non-alcoholic delirium acutum may be unattended by appreciable brain lesion, although usually abundant evidence of either active or passive hyperæmia is found.[2] But Fürstner [3] describes three cases of acute delirium, two fatal, and where in the latter even a microscopic examination of the brain discovered nothing abnormal.[4] Thus it is certain that death may result from a temporary functional exhaustion of the brain centres, as it may from their sudden exhaustion in shock, or in the presence of intracranial tumors.

In one of Dr. Thomas' cases the result was not death, but insanity of some duration, recalling an analogy with puerperal mania. Each case may offer individual peculiarities of lesion, as of absence of lesion, and a temporary arterial anæmia of the brain constantly tends, as in the pseudo-hydrocephalus of Marshall Hall, to determine venous hyperæmia as a secondary result.[5]

MARY PUTNAM-JACOBI, M.D.

HOW TO SEND MANUSCRIPTS.—The best way to send manuscripts is in a stout envelope long enough to hold commercial note-sheets without folding. A similar envelope, stamped and addressed for return of manuscript, should be enclosed. Before setting out to roll a manuscript always commit suicide.—*The Writer.*

[2] Schull: Klinische Psychiatrie, p. 336, Leipzig, 1886. Spitzka pronounces this delirium to be clearly symptomatic of grave somatic disease of the brain.

[3] Ueber Delirium Acutum, Archiv für Psychiatrie, Bd. xi., p. 518.

[4] There had been violent jactitation in the three cases, and the fibre of the voluntary muscles exhibited a wide diffusion of waxy degeneration.

[5] The poets are often singularly successful in depicting the external aspects of this as of other brain diseases. Weir Mitchell, physician and poet, draws a vivid picture of traumatic delirium in a wounded soldier in his novel "War Time." The case, however, is interpreted as septicæmic. Hunt quotes appropriately a passage from "Rab and his Friends" (written by a physician), where a woman, after amputation of her breast, imagines that she is nursing at it a child who had died forty years before, and in the fancy drifts away into terminal delirium and death.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 7 to April 13, 1889.

DYRNE, CHARLES C., Surgeon, U. S. Army. Promoted Surgeon, with the rank of Lieutenant-Colonel, to rank from March 29, 1889.

MUNN, CURTIS E. Promoted from Assistant Surgeon to Surgeon, with the rank of Major, to rank from March 29, 1889.

BROWN, PAUL R., Captain and Assistant Surgeon. By direction of the President will report in person to Brigadier-General John R. Brooke, President of the Army Retiring Board, at Omaha, Neb., for examination by the Board. Par. 9, S. O. 80, A. G. O., Washington, April 6, 1889.

By direction of the President, the State of Wisconsin is transferred from the Department of the East to the Department of Dakota. G. O. 36, A. G. O., Washington, April 6, 1889.

Official List of Changes in the Meaical Corps of the Unitea States Navy for the week ending April 13, 1889.

HEFFENGER, A. C., Passed Assistant Surgeon. Found unfit for duty at present, by Retiring Board, but not permanently incapacitated for active service, and granted one year's leave of absence for medical treatment.

DUBOSE, W. R., Passed Assistant Surgeon. Detached from the U. S. S. Constellation and ordered to the Practice Ship Jamestown.

LOWNDES, C. H. T. Commissioned an Assistant Surgeon in the U. S. Navy, March 13, 1889.

LAPAROTOMY FOR PERFORATION OF THE APPENDIX VERMIFORMIS FIFTEEN HOURS AFTER THE ONSET OF THE ACUTE SYMPTOMS; RECOVERY.

BY ROBERT F. WEIR, M.D.,

SURGEON TO THE NEW YORK HOSPITAL, ETC.

THE following case has several points of interest, which are, first, the earliness and success of the operation; second, the ample proof that it affords of the intraperitoneal nature of the exudations and abscesses that follow a perforated appendix; a spreading peritonitis; third, the fact that antecedent attacks did not ward off, as Mackenzie states they do, by previous limiting exudations, and, fourth, the uselessness of Treves's advice to cover over by peritoneum the cut end of the appendix where removed. The history of the case is this:

Dr. F. A. L——, thirty-four years of age; family history excellent; has had the usual diseases of childhood, but, with the exception of a short attack of intermittent fever six years ago, has always enjoyed a most robust and perfect health; never suffered from any form of dyspepsia or constipation, the bowels moving with regularity every morning. September 26, 1888, complained of general malaise and anorexia; pulse, 90 and temperature, 100° F. During the night there was quite severe abdominal colic, and, with the expectation of being able to relieve this, a long rectal tube was passed, but no flatus escaped. A warm enema was then taken and a slight amount of fæces expelled, but without the result of giving any relief. In the morning there was localized tenderness and some pain in the right iliac fossa and a small tumefaction. Pulse, 100; temperature, 100.5° F. A little later in the day, the colic not having abated and there being a desire to defecate, patient seated himself at stool, and during an effort of straining, not however very powerful, sudden intense pain was felt in the region mentioned, accompanied by immediate sinking sensations, very marked pallor, and copious clammy perspiration. The patient was moved back to bed, a hypodermatic injection of brandy made, hot-water bottles applied, and in a short time he rallied. Morphia was administered by Dr. Henna, who was in attendance, as was required to relieve pain, and hot applications were made to the right iliac region. For three days the temperature was slightly elevated, 100.6° F. being the maximum point, and the tumefaction increased somewhat in size. After that time, for three weeks there was no rise of pulse or temperature, and the tumor gradually diminished to about the dimensions of a hickory-nut.

The patient then continued about his business until October 31st, exactly two weeks after going out, when he was again seized with colic, local tenderness in the right iliac fossa as before, and a rapidly increasing swelling. There were no febrile symptoms. Treatment as before. In a few days the swelling again commenced to subside and after two weeks in bed patient commenced to move about the house.

The foregoing account was furnished by the patient himself.

I saw him first, with Drs. Janeway and Henna, November 22d, and found in the iliac fossa a mass the size of an egg, which however was a diminishing one, and was without fever or abdominal symptoms. This was the recrudescence of his third attack. Advised rest only. About six days later, he not having got out of bed, an aggravation of pain and swelling took place—so much so that the next day was appointed for an exploratory incision; the symptoms by that time, however, ameliorated, and the operation was postponed. He remained in bed some ten days longer, and the swelling then having nearly subsided he got up, and a week later commenced going about, feeling quite restored. On December 23d a medical friend in the country examined him, and could scarcely feel anything in the fossa. On December 25th, after eating quite heartily the day before, he was seized in the morning with a very sharp pain in the right iliac region, more severe and more extensive than on any of the previous occasions, and this was followed by a slight chill, with temperature 100° F. and rapid pulse and vomiting. The latter recurred several times during the day. I was notified on the afternoon of this attack, and made an appointment to see him early the next morning with Dr. Henna, his physician. At 11.30 P.M. the same evening Dr. Henna reported him as no better, requiring larger doses of morphine to quiet him, and the vomiting as persisting though not frequent. I saw him at once, and found great tenderness over the right side, not extending, however, beyond median line; slight but marked dulness was revealed by the moderate percussion permitted; advised etherization for examination and for an explorative operation if that should be thought best.

Under ether a mass the size of a hen's egg was recognized just on the line of the anterior superior spine, and under antisepsis and with the aid of Drs. Henna and Abbe, and with Dr. Birmingham carefully giving ether, an incision three to four inches long in the course of the linea semilunaris was made down to the fascia transversalis, and when this was cut through, the peritoneum was recognized only as a mass of grayish fibrous structure, more like a fibro-sarcoma; so much so that this idea came to my mind. On cutting and tearing carefully through this kind of tissue to the depth of an inch at least, the peritoneal cavity was opened above purposely for exploration, and the finger found the mass to extend along brim of pelvis, lifting up vessels, or rather pushing them toward the median line. The limiting line of this exudation, which was then recognized to be altogether intraperitoneal, was torn through along junction of parietal peritoneum on the inside of the incision, and several coils of intestine, thickly plastered over as far as seen with recent lymph, were brought into view. The wound was strongly held apart and its bottom, which was resisting and elastic, almost fluctuating, carefully inspected to determine whether further dissection should be carried deeper or aspiration resorted to. It was then seen that the base of this cavity, which I had cut or torn open, was composed of the cæcum and appendix strongly agglutinated to the surrounding intestines.

The appendix was coiled on itself, and only after a little time was the attached end made out. Its free end was ulcerated through and was embedded in a mass of soft adhesions enclosing a grumous abscess the size of a small hazel-nut. The appendix, some three inches long with a decided mesentery, was tied off about half an inch from the cæcum. The cavity of the wound was then sponged out with a one to five thousand sublimate solution, smeared with powdered iodoform, and packed with iodoform gauze after a large rubber drainage-tube had

been inserted. The edges of the wound were carefully closed save where the tube and gauze emerged. An attempt was made to cover the divided end of the appendix with peritoneum by sutures, but was abandoned as difficult and, after all, unnecessary. Certainly the prolongation it caused would not pay and previous experience in this operation and in extirpation of the gall-bladder had shown that simple ligation was amply sufficient. At the end of the operation, which lasted fifty-five minutes in all, pulse, 91, and the patient's general condition was excellent.

His progress was eminently satisfactory. Temperature was highest the second day, 100° F. Pulse, 90. Very painful spasm of abdominal muscles, due to the sutures made in the muscular planes, was at times experienced. The appendix was much thickened but patulous; its lumen was, however, only the size of a large probe. Its walls were so thickened and elastic as to suggest before opening that fluid was inside, but none was there. The ulcerated opening was at the very tip. No concretion felt or seen at or subsequent to the operation.

The patient made a speedy recovery, and has been free from any uneasy feelings ever since the closure of the wound.

ON SOME OF THE DEFORMITIES OF THE TARSUS IN CONGENITAL EQUINO-VARUS, WITH A DESCRIPTION OF THE EXTERNAL LATERAL-TRACTION APPARATUS.

By NEWTON M. SCHAFFER, M.D.,

ATTENDING SURGEON-IN-CHARGE OF THE NEW YORK ORTHOPÆDIC DISPENSARY AND HOSPITAL; CONSULTING ORTHOPÆDIC SURGEON TO ST. LUKE'S HOSPITAL, NEW YORK.

We are all acquainted with the difficulties that sometimes attend the treatment of many of the apparently simple cases of congenital equino-varus. If we regard these cases from a purely objective stand-point, it seems a not very difficult matter to relieve the deformity. The resisting gastrocnemius muscle and the tense plantar fascia offer a well-defined and definitely located resistance to the reduction of the deformity; and our prognosis is too frequently based upon these easily determined elements of resistance, coupled with the degree of mobility that may exist at the ankle and tarsus. But a long record of failures points to the fact that there are some elements of resistance in these cases which cannot always be easily determined—elements which are beyond the reach of ordinary diagnostic measures, and which have not always been removed by even the most radical operative procedures.

My studies in this interesting field have led me to seek a remedy for some of the difficulties that present in congenital equino-varus which will insure more uniform and better results; for I feel that all of the cases of this class, if treated before the age of puberty, should recover with straight feet, and I have felt for the past fifteen years that, if a properly applied force could be utilized in these cases, very few, if any, would require operative treatment. In brief, I feel that while much ingenuity has been expended in devising and in perfecting the various cutting methods of treatment, the apparently simple, but really more difficult, mechanical methods which promise so much better results have been in many cases neglected.

It also strikes me that, as orthopædic surgeons, we take too much for granted—that there is not enough original research and study among those who practise orthopædy. The anatomy, both normal and pathological, as well as the mechanics of the articulations, claim more of our attention than has been devoted to them. The surgical aspects of chronic deformities are, as we all know, so well taught, that it is easy enough to apply the knife, the saw, the chisel, or the osteoclast, if we have occasion to use them. But who is there among us who has completely mastered the subject of the mechanics of the articulations? I cannot help thinking that the next generation of orthopædic surgeons will do less operating than is now practised, and that the much-neglected subject of applied mechanics will receive the attention it demands.

There is one popular fallacy in the pathological anatomy of congenital equino-varus that has not received the attention it deserves.

We are taught that there is no lateral motion at the ankle-joint; that the articulation between the inferior articulatory surfaces of the tibia and fibula and the superior and lateral articulatory surfaces of the astragalus permit only antero-posterior motion, except in extreme extension. As a consequence, we have been taught by many eminent teachers that in congenital equino-varus the principal deformity occurs at the articulation of the calcaneus with the cuboid on the outside of the tarsus, and at the articulation of the astragalus with the scaphoid on the inside of the tarsus—these two transverse joints forming the medio-tarsal articulation.

No one, I think, will deny that some of the major deformities that occur in congenital equino-varus depend upon the changed relations of the bones of the tarsus at or below the calcaneo-astragalar articulation, and no one, I think, will doubt that the medio-tarsal joint plays an important part in the deformities of club-foot. But I wish to assert that the deformity or deformities which occur at the medio-tarsal joint are neither the most important nor the most difficult to remove. If the medio-tarsal deformities were all, or the most important ones, found in equino-varus, my experience leads me to say that our results would be uniformly better.

I do not doubt that anatomists are correct in saying that there is no perceptible lateral mobility at the normal ankle-joint. But it is, I think, absolutely certain, clinically and pathologically speaking, that a very considerable and a very important displacement of the astragalus occurs in congenital equino-varus, accompanied in some cases by an intrinsic deformity of the neck of this bone. And I believe that the most important deformity of congenital equino-varus, as well as the most difficult one to remove, occurs at the very point at which many anatomists tell us it cannot occur.

The astragalus is closely held between the two malleoli; it articulates with the calcaneus and scaphoid bones only, and it is the only important bone of the tarsus which is not directly controlled by muscular action. Lying in its doubly protected position and held in place by its ligamentous attachments, it can only be reached, when we desire to correct the position it assumes in the condition under consideration, by attacking the bones with which it articulates. All the other bones of the tarsus are reached with comparative ease; but the astragalus can only be reached by an indirect force.

If, under these circumstances, we divide the plantar fascia and the gastrocnemius and all the other tissues ordinarily divided in the operative treatment of congenital equino-varus, we cannot, as we all know, insure a reduction of the deformity. We may even make a deep open incision into the plantar tissues and cut the anterior portion of the internal lateral ligament of the ankle-joint, and divide the tendo Achillis, without successfully reaching the displaced and rotated astragalus. Still further, osteotomy may be performed and a large wedge removed from the outer side of the tarsus, and still leave the rotated astragalus unmoved in its deformed position. In brief, I believe that the keystone of the deformity is at the misplaced astragalus; and that, if we succeed in replacing it in its normal position, the other deformities become of minor importance and are comparatively easily removed.

What is the position of the astragalus in congenital equino-varus? Sometimes, though we cannot always discover it, especially in young subjects, there is an intrinsic deformity of the head and neck of this bone, due, I am quite sure, in the majority of cases to rapid growth during the latter months of intra-uterine life, after the gastrocnemius has become shortened; but whether this intrinsic deformity exists or not it is apparent that the ac-

quired position of the astragalus in the condition named is not a simple one.

Rather than attempt to describe the malposition of the astragalus relatively in the condition under consideration, I think it better to study its position from a mechanical stand-point. We can then better understand the indications for treatment.

In response to the irresistible force which is acting upon all the misplaced tarsal bones through the medium of the shortened muscular and fibrous tissues, the astragalus becomes rotated, first, upon a *transverse axis; i.e.*, the head and neck are tilted downward as it is in the position of extension of the ankle-joint, or as it is in simple equinus. Secondly, it also becomes rotated upon an *antero-posterior axis*—or its under-surface is turned toward the mesial plane of the body upon an axis which corresponds, in general terms, with the long diameter of the foot. And, thirdly, it is rotated upon a *vertical axis*, or the head and neck are twisted toward the mesial plane of the body upon an axis which corresponds with the long diameter of the tibia, aiding in the production of the so-called inversion or adduction of the tarsus. In a typical case we find all these rotatory elements of deformity present, not only at the astragalus but also at all the other tarsal bones, producing a compound deformity that so disturbs the normal line of gravity that the patient in walking presents the cuboid bone to the floor.

A brief study of the anatomical construction of the tarsus, bound together as its component parts are by strong ligaments, will, I think, convince anyone that the extreme malposition of the cuboid bone (as a matter of illustration), and which is seen in all extreme cases of equino-varus, could not occur except as a result (1) of a dislocation at the calcaneo-cuboid articulation; or (2) a dislocation at the calcaneo-astragalar articulation; or (3) a malposition of the entire tarsus, accompanied by a greater or less elongation of all the ligaments on the concave side of the deformity, and a changed relation of all the articular tarsal surfaces. It is known that there is no true dislocation of any of the bones of the tarsus under the conditions named. The articular surfaces are disturbed, subluxation to a minor degree is present, and interarticular pressure is concentrated at certain exposed points. It seems evident in these cases that there is, among other things, a loss of relative growth between the muscles and the bones—especially the long bones of the leg—and that the arrested or impaired growth of the gastrocnemius produces a malposition that prevents the foot from assuming a normal position. Growth of the bones, however, goes on, and the result is that the tarsus, like every other complex body, yields in the direction of the least resistance. As the tarsus yields in response to the irresistible force of opposed bony growth, the os calcis, the cuboid, and the scaphoid are pulled, so to speak, from their normal position, dragging the astragalus with them after their ligaments have been stretched to their utmost capacity. In short, a certain degree of displacement of the astragalus takes place, and this is largely due to the fact that the superior articular surface of the astragalus, as well as the lateral facets, are from ligamentous or muscular attachments, and also because the ligamentous attachments of the lateral, as well as the anterior and posterior surfaces of this bone, are low down, or *below* the centres of rotation, to which attention has been called. There is, therefore, no ligamentous or direct muscular resistance to the rotation of the astragalus when the os calcis, the cuboid, and the scaphoid are drawn from their positions. The ultimate point of resistance lies, therefore, at the inferior articular surface of the tibia and fibula, and, as a result of the great and prolonged pressure which exists, it may be presumed that absorption of the articular cartilage ensues, and this, with the slight rotation of the fibula upon the tibia upon their long axes, accounts for some of the lateral or rotatory movements which the astragalus undergoes in the deformity under consideration. Even absorption of bone may follow, and it is not impossible that the ligamentous structures which bind the fibula and tibia together may yield as the result of the long-continued pressure, or that—especially in fœtal life—the astragalar neck may become twisted.

Associated with the shortened gastrocnemius in congenital equino-varus, we always have a shortening of the plantar tissues. This plantar shortening fixes the calcaneus in a position where it cannot rotate outward—this latter condition occurring only, as a rule, in flat-foot with elongated plantar tissues, or in valgus with a paralysis or weakness of the gastrocnemius. An important feature of congenital equino-varus is, therefore, an inward rotation of the calcaneus upon an antero-posterior axis, associated with a rotation upon a transverse axis.

After the remarks made upon the nature of the muscular shortening, we will assume that the normal longitudinal growth of the gastrocnemius is either arrested or impaired, and that the tibia is not affected to the same extent by the lesión or change which produces the so-called contracture of the muscles. If the tibia outgrows the muscle, and as a result of the irresistible force produced by longitudinal osseous growth in the long bones of the leg, a deformity must occur somewhere. In congenital equino-varus it is first seen in the rotation upon a transverse axis and in the complex rotation of the os calcis already referred to. Perhaps the tibialis posticus is also affected, as I think it is in many instances. The plantar tissues certainly are shortened. With these elements at work the deformity of equino-varus is not difficult to explain, from a mechanical stand-point. The whole tarsus is rotated like the key-stone—the astragalus—upon the three axes already mentioned. The hinge of this rotation, so to speak, is at the point of the least ligamentous and muscular resistance—the tibio-astragalar articulation—and, as a result of the prolonged and uninterrupted pressure, the whole tarsus assumes a position of chronic deformity, the various articulations becoming more rigid as time passes.

It is well to stop here for a moment to point out the conditions which the ligaments of the tarsus assume under these conditions. On the outer aspect of the foot they become elongated; on the inner, they soon become very materially shortened. This is especially so at the internal lateral ligament of the ankle-joint. All the other ligaments become either lengthened or shortened, depending upon their location and their relation to the acquired position of the bones to which they are attached—those on the convex side being elongated, those on the concave side being shortened.

After a time—but I think after a much longer time than is generally supposed—the articular surfaces of all the bones involved adapt themselves to the deformed position. My experience leads me to think that it is exceptional for the osseous troubles to reach a point of more than troublesome resistance before puberty unless there is a considerable intrinsic deformity of the neck of the astragalus; while the ligaments, on the other hand, become very much shortened, even in babyhood.

I feel therefore that we may assume the following as a basis to treat the condition under consideration: 1, That there is a compound deformity in equino-varus due to a rotation of all the bones of the tarsus upon three distinct axes, viz., transverse, antero-posterior, and vertical; 2, that this compound deformity is due to a loss of relation between muscular and osseous growth—not to muscular contraction or contracture, as has generally been supposed; 3, that the principal obstacles to a reduction of the deformity are (1) the position acquired by the astragalus (with or without an intrinsic deformity of the neck) and (2) the ligamentous shortening; 4, that these difficulties are much increased by the progressive ligamentous and osseous changes that occur as the direct result of prolonged malposition; and, 5, that the deformities of the medio-tarsal joint are secondary in importance to those which occur at the astragalus.

We will now pass to the question of treatment.

In undertaking any plan of treatment we must bear in mind that the whole tarsus is involved, and that any method which restores the astragalus to its normal position promises to be successful; for if we succeed in restoring the normal relations of the astragalus to the tibia we carry with it (the astragalus) the other bones of the tarsus. My experience proves that it is not the antero-posterior deformities, where rotation occurs upon a transverse axis only, that present difficulties. The real difficulties occur in the so-called "lateral" deformities, where we see the effects of the compound rotation, to which attention has already been directed. In order to make myself better understood, I will again briefly refer to the three varieties of rotation: The first named, *the transverse*, which is shown at the elevated heel; the second, *the antero-posterior*, is evident at the inward rotation of the os calcis; the third, *the vertical*, is seen in the inversion of the entire foot.

The result of the first-named condition, as has already been stated, is easily overcome if it be uncomplicated. The second and third conditions are due largely to the causes which produce the first, and may be considered as secondary to it.

Our first effort, therefore, should be to attack the gastrocnemius-shortening in such a way as to overcome its secondary effects; and it must be evident that any method which neglects the gastrocnemius-shortening must fail. But the entire tarsus is rotated, and we must not make the error of using the cuboid as a point of resistance to overcome the rotation of the tarsus, for the simple reason that if we do so we at once block the mechanism, whatever it may be, designed to overcome the rotation of the tarsus. The cuboid has taken its acquired position on account of its close relation with the os calcis. The tarsus, as a whole, should be thrown *downward and outward* (reversing the curve of the deformity, which is *inward and upward*), on an antero-posterior axis, to *outward* upon the same axis, and this downward and outward rotating force should be applied upon a remote axis until the os calcis and the astragalus fall directly under the tibia—the mechanism being so arranged that the rotation upon a transverse axis is also attacked. We must also remember, in treating all these cases—even those seen immediately after birth—that we are not dealing with muscular shortening only. Two other potent factors must be considered, and these are: 1, The resistance which exists at the shortened ligamentous structures; and, 2, a possible or even probable intrinsic deformity of the neck of the astragalus. And it must be remembered that these ligamentous structures soon adapt themselves to the acquired position of the bones of the tarsus. It is surprising how soon these ligaments shorten, and this remark is especially true of the internal lateral ligament of the ankle-joint. Any procedure which ignores this condition or the changed articular surfaces is apt to result in failure. And the difficulty of attacking these shortened ligamentous tissues, especially those upon the internal malleolar aspect of the ankle, is apparent. It is very easy to apply traction to the antero-posterior contractions—of whatever nature—but it has not been so easy, heretofore, to reach the internal lateral ligamentous contractions, or the twisted astragalar neck by this same method of traction—though it seems evident that the resistance of a contracted ligament or a deformed bone is just as important as that of a shortened muscle, and much more difficult to reach. And this principle of lateral traction should not be applied without recognizing the fact that the cuboid bone must rotate downward and outward with the other bones of the tarsus upon a remote centre of motion in removing the deformity of equino-varus. My experience has proved that if the whole foot is rotated outward upon a remote centre by an adequate mechanism, the heel being properly secured, the major deformities become modified very soon.

In my experience the principal obstruction to the reduction of the deformity (excepting, of course, an intrinsic deformity of any of the tarsal bones) exists in the shortened ligamentous tissues which lie between the inner malleolus and the tarsus. I formerly regarded the plantar tissues as being the most obstinate—and they still tease us all. But the internal lateral ligament of the ankle is very strong and dense. It arises from the internal malleolus, and sends its radiating fibres not only to the os calcis and scaphoid but to the astragalus as well. This ligament is always shortened in congenital equino-varus, and the tarsal bones to which it is attached are imprisoned in their acquired positions until the contracted portions of the ligament are elongated. I regard this ligamentous resistance as being far more important than the gastrocnemius or plantar shortening. If we can find some means to overcome this shortening of the internal lateral ligament, I am sure that we will find that the duration of the treatment of congenital equino-varus will be very materially shortened, and much better and far more permanent results will be secured.

The apparatus I will show you to-night treats the internal lateral and other ligamentous resistance exactly as the gastrocnemius is treated in our efforts to overcome the antero-posterior contractions of equinus with the antero-posterior traction-shoe.[1] The aim of this new traction-apparatus is to bring the rotated tarsus, as a whole, and by a very simple movement, directly under the inferior articulating surface of the tibia, attacking not only the post-tibial resistance, but also, and especially, the stubborn shortening of the internal lateral ligament, as well as all the other contracted tissues upon the inner or concave side of the deformity. If the neck of the astragalus is twisted, a very great force is applied to it in the right direction. I had previously attempted to accomplish these ends by a pushing force, acting from the

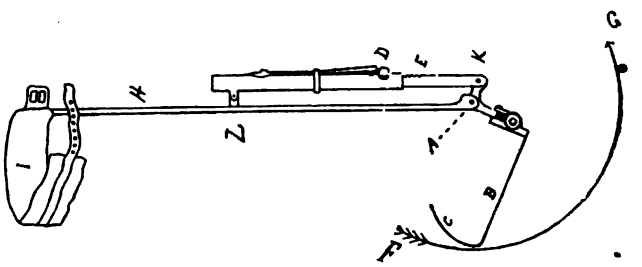

FIG. 1.

inner side of the foot (the internal lateral-traction shoe). But experience proves, in a very limited number of cases, that it is difficult to apply the rotating force accurately when using this internal lateral stretcher, and it was also found that the rotation of the cuboid was sometimes arrested by the mechanism of the apparatus before it fell into its proper position. And it may be that a sufficient force could not be obtained in cases where there was an undiscovered twist at the neck of the astragalus, a criticism which cannot be made of the external-traction shoe, which can be made a "crusher" if necessary.

In the apparatus I now show you, while sufficient pressure is exerted upon the cuboid by a simple retention-strap to make it a simple point of resistance, the apparatus is so arranged that the whole tarsus is rotated *downward and outward* to any desired extent; and a direct pressure is exerted in the right direction upon the twisted astragalar neck, if any deformity exists at that point.

In Fig. 1 there is shown a schematic engraving of the external lateral-traction apparatus, illustrating its application to a condition of equino-varus of the left foot, and its movement upon a remote antero-posterior axis. The centre of motion is at the point A, remote from the tarsus and outside of, but directly over, the external malleolus. The anterior portion of the foot rests upon the foot-piece

[1] Vide The Use of Traction in the Treatment of Club-foot, New York Medical Journal, March 5 and 12, 1887.

B, inside of the curved lateral plate C, which grasps the inner aspect of the foot at the junction of the first metatarsal bone with the first phalanx of the great toe. The heel is retained by the conventional astragalar retention-strap, and the heel traction-strap of the antero-posterior-traction apparatus. The foot-plate of the apparatus is removed posterior to the point which corresponds with the junction of the tarsus and metatarsus, leaving an open and unobstructed space for the descent of the heel when traction is applied. The necessary arrangements to secure the heel, etc. (not shown in this engraving), are the same as those used in the application of the antero-posterior-traction shoe, which is described in full in the *New York Medical Journal* for March 5 and 12, 1887.

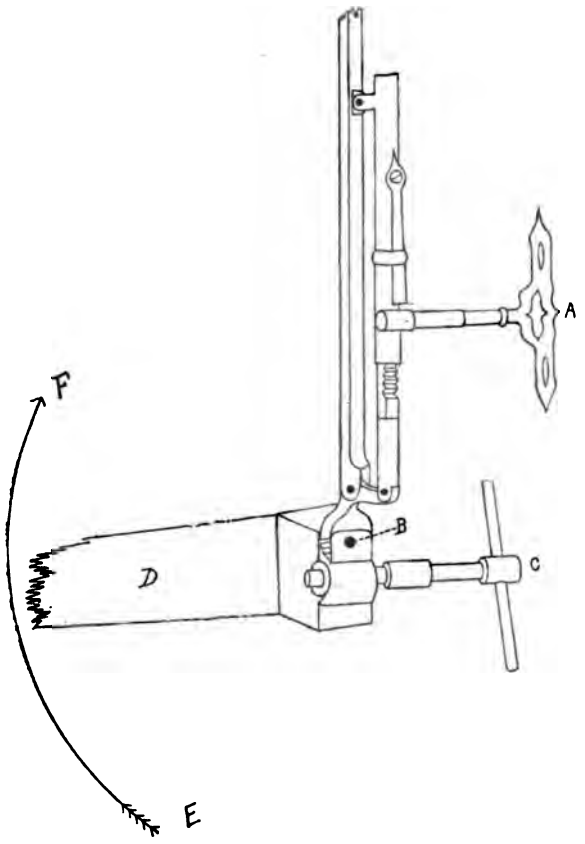

FIG. 2.

The foot being secured by the straps referred to, in the apparatus now under consideration, in its deformed position (at the angle, for example, shown in Fig. 1), a key (A, Fig. 2) is introduced at the cylinder D, and the extension rod E is *shortened*. The entire foot-piece of the apparatus is thrown downward and outward by this movement in the direction of the curved arrow F, upon the remote centre A, and the foot, properly secured in the apparatus, follows the same movement.

The foot-mechanism is attached to a straight, strong steel bar, H, and this side-bar is surmounted by a conventional calf-band, I, which is made to closely encircle the calf at a point just below the knee-joint. The retraction-rod is attached to the side-bar at L. In varus this side-bar, H, is placed on the outside of the leg—in valgus on the inside. In difficult cases this side-bar may be continued upward so as to include both leg and thigh, with a perineal pad to afford a point of counter-resistance to the force applied below. But in any event, and in order to secure a proper adjustment of the apparatus and to exert an adequate force in the right direction, the leg-piece of the side-bar H should be directly over the fibula, and at least one inch away from it at the external malleolus, in the treatment of equino-varus.

Fig. 2 gives a side-view of the apparatus, and illustrates the action of the apparatus upon a transverse axis. The centre of motion on a transverse axis is at the point B, the key C acting on a worm and screw which lowers or elevates the anterior part of the apparatus, D. The foot being retained in the apparatus by the astragalar and heel retention-straps already referred to, and secured in the exact position of the deformity, the initial force is applied by turning the key C so as to move the anterior part of the apparatus, D, in the direction indicated by the curved arrow E F, until a considerable resistance is offered by the shortened tissues of the foot. Then the key A is used, the outside retraction bar and rod is forcibly shortened, and the whole foot rotates downward and outward, as indicated by the curved arrow F G in Fig. 1.

The curved lateral plate C (Fig. 1) can be moved at will and secured by a key and clamp in any desired position, thus meeting any ordinary amount of inversion of the anterior portion of the tarsus. In short, it is not ordinarily necessary to make any special provision for the rotation of the tarsus upon a vertical axis. When, however, any special mechanism is necessary, that attached to the foot-plate of the "internal lateral-traction apparatus" (described in full in the *New York Medical Journal*, March 5 and 12, 1887) meets all the indications. In some cases I have used this attachment with advantage, but in almost every case the vertical rotation has yielded to the combined force represented in the accompanying engravings.

In ordering this apparatus, the centre A (Fig. 1) can be placed at any desired point, and its position will vary with the extent of the deformity, the amount of force required, etc. The same remark applies to the arm A K (Fig. 1), which can be lengthened or shortened as occasion demands. It is easy to see that, with the combined force exerted by both these powerful levers, an osteoclast could easily be constructed, and I am now having one made with this end in view.

I am indebted to my friend Dr. Charles L. Scudder, of Boston, for his assistance in the preparation of the engravings which accompany this paper, as I also am for his recent contribution to the etiology of club-foot.[1]

MARRIAGE AND BIRTH STATISTICS IN ENGLAND.—It is said, in the *Pall Mall Gazette*, that each year 15 people out of every 1,000 marry. Of each 1,000 men who marry 861 are bachelors and 139 are widowers, while of each 1,000 women only 98 have been married before, and 902 are spinsters. Twelve marriages out of every 100 are second marriages. The average age at which men marry is about 27, while the average age at which women marry is about 25 years. Out of every 1,000 persons 602 are unmarried, 345 are married, and 53 widowed. Over one-half of all the women between 15 and 45 are unmarried. In all countries about 5 per cent. of marriages prove barren. Among the English nobility 19 per cent. are childless. Married women live two years longer than single ones, although 1 in 70 dies in childbirth. If the mother dies first, the father survives 9½ years; but if the father dies first, the survival of the mother is 11½ years, as an average. Two thousand four hundred and forty-one births occur in England daily, about 33 for each 1,000 inhabitants. February is the month in which the greatest number of births occur, June the month in which occur the fewest. The average number of births for each marriage is 4.33. In every 1,000 births 11 are twins.

TREATMENT OF ACUTE BRONCHITIS IN THE EARLY STAGES.—The following is recommended by Dr. H. C. Wood as remarkably efficacious in the abortion of an attack of acute bronchitis:

℞. Potassii citratis..... ℥j.
Syrupi ipecacuanhæ..... f℥j.
Succus limonis..... f℥ij.
Aquæ..... ℥iij.
M. S.—Two teaspoonfuls every two hours.

---

LOCALIZED BASAL MENINGITIS AND DOUBLE OPTIC NEURITIS.[1]

By WM. M. LESZYNSKY, M.D.,

LECTURER ON MENTAL AND NERVOUS DISEASES AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; NEUROLOGIST TO THE DEMILT DISPENSARY; ASSISTANT PHYSICIAN AT THE MANHATTAN EYE AND EAR HOSPITAL, ETC.

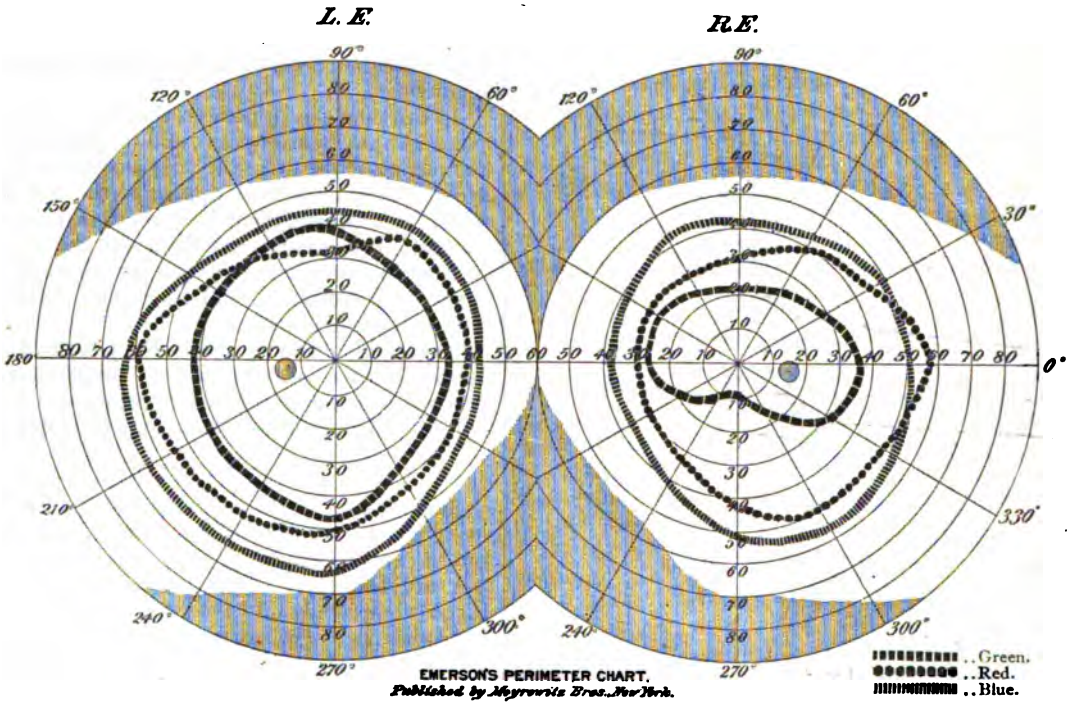
THE patient to be presented this evening, whose history is the text of this paper, has been under my personal supervision, at short intervals, during the last five years. As a demonstration of the advantage of an early recognition of serious symptoms, and as an exemplification of the value of systematic observation extending over a prolonged period, he may be considered an exceptional illustration.

F. M——, sixteen years of age, and employed as an errand-boy, first came under observation November 22, 1883, with the following history: Present illness began eight months ago with constant frontal headache, which still persists. Frequent attacks of nocturnal vomiting occur without known cause. He awakes at night, suddenly empties the stomach, without previous nausea, and then lies down and sleeps comfortably until morning. He also vomits occasionally during the day without warning, the attack occurring independently of the ingestion of food. Has never complained of vertigo or subjective eye-symptoms. Appetite good; bowels constipated. Generally sleeps well. During the last six months treatment has been directed to his stomach, without benefit. Headache is the principal symptom for which he seeks relief.

His mother, who accompanies him, says that she and her husband are healthy. Patient was a well-developed infant at birth, and experienced the usual diseases of childhood. About two years ago he had scarlatina, without symptoms of renal complication. There is no family history of syphilis or tuberculosis. His head has never been injured by a blow or a fall. He has no evil associates, and is not addicted to any objectionable personal habits.

Present condition.—Intelligent, anæmic-looking lad. The pupils are equally dilated to 27 mm., and react normally. There is no hypersensitiveness to pressure over the supraorbital nerves, nor upon percussion of skull. The tongue is protruded well, is slightly tremulous, and has a moderate amount of "coating." Pulse, 80, regular, feeble, and compressible. Rectal temperature, 99° F. With outstretched hands, there is well-marked tremor in both upper extremities, which, in view of his anæmic condition, cannot be considered of much diagnostic significance. No ataxia. Grasp, with dynamometer, registers, right, 82; left, 72. Gait and muscular resistance, good; knee-jerks and skin reflexes, normal. Heart, lungs, and abdominal organs present no abnormalities. Examination of urine, negative. The only positive objective symptom is discovered upon ophthalmoscopic examination, which reveals double optic neuritis vision. Right eye = $\frac{20}{20}$; L. = $\frac{20}{15}$; fields, normal. Both disks are swollen, and their outline obliterated; elevation of right = + 3 D.; L. = +5 D. The arteries are small, and the veins are much enlarged and tortuous, both being partly obscured by the opacity of the papillæ. The inflammatory process has invaded a portion of the surrounding retina, but there are no hemorrhages. The region of the macula is free from œdema or exudation.

December 24th, one month later.—The urine has been frequently examined and found to contain triple phosphates; otherwise normal. Under treatment the headache and vomiting have become less frequent. V. R. = $\frac{20}{30}$; L. = $\frac{20}{100}$; H. at disk: R. = 4 D.; L. = 1.5 D. In comparing the swelling of the disk with the acuteness of vision, it is interesting to note that while the elevation of the nerve in the left eye measures 1.5 D. and the vision is but $\frac{20}{100}$, that of the right is $\frac{20}{60}$ with an elevation of 4 D. In this instance the acuteness of vision appears to be inversely proportionate to the degree of swelling.



January 10, 1884, about four weeks later.—He was improving in general health; tremor in hands diminished; headache and vomiting have subsided, but the swelling of the optic disks has decidedly increased since last note; right = + 5 D.; left = + 6.5 D. There are also signs of effusion into the retina.

June, 1884.—During the last six months occasional attacks of headache and vomiting occurred. In the month of February left-sided tinnitus began, and has continued, with short intermissions, to date. The retinal effusion gradually diminished and has entirely disappeared. The elevation of the disks has varied from time to time. At present V. R. = $\frac{20}{30}$; L. = $\frac{20}{60}$; right disk = + 3 D.; L. = + 5.5 D. He is gaining in weight and improving in appearance.

January, 1885, over a year since his first visit.—Has been quite well during the last six months; no headache,

[1] Read before the New York Neurological Society, March 5, 1889.

vomiting, or tinnitus; the optic neuritis has been slowly subsiding; V. R. = $\frac{20}{70}$; L. = $\frac{20}{50}$; disk, R. = + 3.5; L. = + 4.

October, 1885.—Remained well during the year; the optic neuritis has been gradually receding, and the disks are beginning to look atrophic; V. R. = $\frac{20}{70}$; L. = $\frac{20}{50}$. There is concentric contraction of the visual field of right eye; left field normal.

October, 1886, a year later.—He continues in good health; vision has improved in right eye, which equals $\frac{20}{40}$ +; left = $\frac{20}{30}$ +; both fields are found to be normal.

November, 1888, five years since first appearance.—V. R. = $\frac{20}{30}$; L. = $\frac{20}{30}$; both nerves atrophic; color perception perfect; perimetric fields for white, normal; left color-field irregularly contracted in different meridians for blue, red, and green; right field contracted in all meridians, more marked for green.

For the benefit of those unfamiliar with the visual field for colors, I append the method of Landolt[1] as described by Jules:[2] "In testing the limits of the field for colors, Landolt found that when colors of great intensity, such as those of the solar spectrum, are used, they can be recognized quite up to the limits of the field for white. When, however, ordinary disks of colored paper of about two centimetres in diameter are used in the manner above indicated for white, it is found that the peripheral portions of the retina are less easily excited by colored than by white disks, and that each color has its own limits, beyond which it ceases to be perceived by the retina. Thus, if we test the normal eye with the fundamental colors—blue, red, and green—in ordinary bright, well-diffused daylight, we find that, on passing the test-object from the periphery toward the centre, the blue is the first to be recognized, after that the red, and next the green. If the fields for each of these colors are respectively taken, and their outlines marked with colored pencils, we obtain a chart similar to that represented in the accompanying diagram. Thus we find that the field for blue is almost as large as that for white, that it is larger than that for red, while the field for green is considerably smaller than that for red. Of the other colors of the spectrum the field for yellow is very similar to that for blue; the field for orange exists between the limits of the yellow and the red. Violet is a difficult color to test; it appears for a considerable distance as blue before its color is really recognized as violet. The three fundamental colors—red, green, and blue—are really all that are required in practice. The limits of the normal fields for color are necessarily difficult to fix with accuracy, because, as we have seen, the sensibility of the retina varies with the intensity of the color and the brightness of the illumination, and the acuteness of vision for color is much less marked at the periphery than toward the centre of the field.

From a number of experiments on this subject Landolt is of opinion that the following should represent the minimum extent of the normal visual field for colors:

	Blue.	Red.	Green.
Upper	50°	35°	30°
Outer	80°	70°	55°
Lower	55°	45°	35°
Inner	50°	40°	30°

Other observers, however, consider that the normal limits are considerably less than this. This difference of opinion is doubtless owing to different conditions in experimenting.

The treatment during the early period of the illness was rest, diet, the relief of constipation, first by calomel, and later by suitable food. Subsequently mercurial inunction, followed by increasing doses of iodide of potassium, and iodide of iron with cod-liver oil. He wore smoked glasses, and when retinal effusion appeared depletory measures were adopted. All treatment was discontinued about two years after his first visit.

[1] Dr. E. Landolt: Examination of the Eyes. 1887.
[2] Ophthalmic Science and Practice, p. 232. 1884.

Since his restoration to health a period of four years has elapsed, and he has been steadily employed at his usual vocation without a recurrence of the slightest manifestation of his former illness. As he appears before you his condition is that of perfect health, with the exception of apparent atrophy of both optic disks. Two samples of urine were recently examined and found normal.

My friend Dr. David Webster has kindly sent me the following report of the result of his examination, made February 8th of the current year:

"I find that F. M—— has well-marked atrophy of both optic disks. The disks are bluish-white and their margins ragged-looking. Around the discal borders, and especially above both disks, there are patches of connective-tissue changes, and the principal retinal vessels are more or less tortuous, though nearly of normal size. By gas-light, R. V. = $\frac{20}{30}$ −; L. = $\frac{20}{30}$ + (three letters out of seven in $\frac{20}{20}$). That he sees so well with such atrophic-looking disks is, to say the least, gratifying."

To recapitulate the salient features of this case: A somewhat anæmic young man appeared five years ago, when sixteen years of age, complaining of constant frontal headache and frequent attacks of causeless vomiting. Well-marked double optic neuritis was the only objective symptom. His parents were living and healthy. No family history of syphilis or tuberculosis could be obtained. He had never received any injury to his head, nor had he been subjected to toxæmic influences. Symptoms of illness began eight months before consultation. About fourteen months previous he had scarlatina. Careful and repeated interrogation of his parents failed to elicit any evidence to prove that renal complication existed during the attack. The headache and vomiting, and subsequently tinnitus, continued with irregular intermissions for about fourteen months. The optic neuritis did not show signs of recession until six months later. The vision was at no time seriously interfered with, and his progress toward complete recovery, with the exception of a trifling impairment of sight, has been almost uninterrupted.

To what pathological process can we attribute this association of symptoms, and what was the nature of the primary lesion? (Without a view of the ocular fundi and the discovery of double optic neuritis, a rational diagnosis would have been impossible.) We may safely exclude syphilis, tubercular disease, malarial toxæmia, lead encephalopathy, and orbital lesions.

Repeated examinations of the urine fail to indicate any affection of the kidneys. In the absence of pronounced or discoverable focal symptoms, the diagnosis, which is necessarily speculative, can only be made by exclusion, and rests between intracranial tumor and localized basal meningitis.

That headache, vomiting, and double optic neuritis are non-localizing symptoms, is a universally accepted fact. That this symptom-complex is suggestive of an intracranial neoplasm, or indicative of an irritative pathological process within the skull, cannot be doubted. The absence of a tubercular or syphilitic history, or any of their objective constitutional manifestations, and the progress of the case toward ultimate and complete recovery, militates against the diagnosis of tumor. The remaining evidence, then, seems to be in favor of a chronic inflammation, most probably in the form of chronic meningitis.

A careful consideration of the foregoing analysis impresses me with the belief that the primary lesion in this case was a circumscribed basal meningitis, non-tubercular in character, resulting from, or induced by, the constitutional state accompanying or following scarlatina.

There being no cranial nerve paralysis, it may be assumed *a fortiori* that in all probability the meningitis was confined to the neighborhood of the optic chiasm, producing the neuritis by extension of the inflammatory process along the structure of the optic nerves.

The complication of optic neuritis following the specific fevers has been observed and recorded by v. Graefe

Nagel, Wadsworth, Allbutt, Gowers, Leber, and Bouchut.[1]

It is beyond the scope of this paper to enter upon a discussion of the pathogeny of optic neuritis, or its relation to intracranial tumor. (A complete and logical analysis of the prevailing theories may be found in Bramwell's[2] recent work, also in Gowers' "Medical Ophthalmoscopy," and is too well known to need more than passing reference.)

The most interesting clinical feature of this case is the pronounced optic neuritis. This condition received the attention that its importance demanded for nearly a year before any signs of recession were noted.

Another instructive fact is the lack of relation between the degree of inflammation in the optic nerves and the visual power. (See table.) This observation is particularly mentioned in order to emphasize the dictum that a high grade of optic neuritis and normal vision may coexist. *Vice versa*, a comparatively slight or moderate degree of apparent neuritis may be present and blindness may result. Similar observations are recorded by Hughlings Jackson, Gowers, Hutchinson, Mauthner, Schweigger, Landolt, and others. Dowse[3] tells us that optic neuritis, without impairment of ordinary visual power, has been known through the researches of ophthalmologists since the introduction of the ophthalmoscope. Optic neuritis being present in the majority of cases of intracranial tumor, at some time during its course, we can readily understand how difficult it often is to differentiate tumor from basal meningitis.

Table showing the Acuteness of Vision as compared with the Swelling of the Optic Disks.

NOTE.—All examinations were made under similar conditions of light, etc., between the hours of 3 and 4 P.M., at the Manhattan Eye and Ear Hospital, and in every instance verified by my friend Dr. David Webster, who kindly interested himself in the case.

As it is often produced in cases of brain tumor by the development of secondary meningitis, there is no reason why a primary basal meningitis should not prove equally potent in its production.

It has been said that the neuritis may either pass off when the gross disease causing it remains; or the progress of the primary lesion may be held in abeyance while the inflammatory process affecting the optic nerves persists, or even increases. In my patient the meningitis probably got well, while the neuritis remained and required special attention.

[2] Intracranial Tumors, p. 67 1888.
Med. Press and Circ., xxvii., 519. London, 1879.

Stephen Mackenzie[1] is of the opinion that "optic neuritis is so commonly symptomatic of some adventitious intracranial product, or of some gross intra-cranial lesion, that a diagnosis often turns on this one point." That it is not always indicative of coarse intracranial disease is shown by the remarkable cases reported by Noyes (1873), and Hughlings Jackson (1876). Mauthner[2] also speaks of patients exhibiting many of the symptoms of brain tumor (severe headache, vomiting, optic neuritis, paralysis of cranial nerves, etc.), where upon autopsy no gross lesion was discovered.

Most clinicians hold that the diagnosis of circumscribed basal meningitis *intra vitam* is impossible, while others doubt the existence of such a primary affection.

There can be no doubt that localized basal meningitis exists both in an acute and chronic form, this fact having been clearly demonstrated by the post-mortem examinations of 47 cases of this affection collected by Gintrac,[3] of which 43 were of the acute variety, while only 4 were chronic in character. Strümpell[4] recognizes that "certain rare cases of chronic circumscribed meningitis cannot be differentiated from a tumor. They generally occur at the base, lead to a considerable thickening of the tissues, and may simulate all the symptoms of a new growth in this region."

Gowers[5] says, "attacks of local meningitis without discoverable cause are very rare, although in a slight and transient form it is possible that they are not quite so uncommon as is usually assumed."

Most observers agree that there is no distinctively characteristic appearance of the optic disks which will enable us to diagnose meningitis from tumor. Mauthner,[6] however, is of the opinion that "if in a case of optic neuritis there is a difference in the refraction between the base and summit of the disk equalling four dioptrics, the diagnosis of tumor is justifiable." While Gowers[7] believes that "a slight degree of neuritis may be due to either tumor or meningitis, but an intense neuritis with considerable swelling and hemorrhages is practically conclusive of tumor."

These views cannot be accepted as conclusive, and require further confirmation.

In a clinical lecture delivered in 1878, Dr. E. C. Seguin[8] presented three children whose symptoms closely resembled those of my patient, the only difference being the absence of strabismus in my case. The following is a brief outline of their histories, with Dr. Seguin's conclusions:

CASE I.—An anæmic girl, aged six, complaining of headache for two or three weeks, with strabismus of one week's standing. No fever, spasm, or delirium; frequent vomiting and marked constipation. To the ophthalmoscope is due the discovery of the most important symptom—double neuro-retinitis.

Diagnosis.—Basal meningitis, localized about the chiasm of the optic nerves, probably without tubercular deposit. Under the use of potassium iodide and blistering the headache and vomiting have ceased, and improvement has begun.

CASE II.—Girl, aged four. Previously healthy. Symptoms, which began five weeks ago, were: dulness, irritability, headache, and vomiting, followed two weeks later by internal strabismus. No fever, spasm, or delirium. Double neuro-retinitis is present.

Diagnosis.—Non-tubercular localized basal meningitis. Potassium iodide was given. The strabismus disappeared within a few weeks, and the neuro-retinitis gave place to atrophy of both optic nerves, which fortunately was slight, so that vision remained nearly perfect.

CASE III.—A girl, aged five, with a history of "chicken-

[8] Hosp. Gaz., March 1, 1878.

pox" a month ago, without fever or apparent ill-health. No headache or irritability, or other symptom, at the present time. Internal strabismus appeared two weeks ago, and has persisted. There is well-marked double optic neuritis. "Neuro-retinitis existed in all the cases cited. But other important symptoms of intracranial disease, such as convulsions, delirium, paralysis, fever, irregularity of the pupils and of the pulse-rate were absent. In none of these cases was the basal disease secondary to any serious general fever or constitutional state." . . . "While regarding the lesion as an inflammation of the pia mater, I do not believe that it is tubercular, because of the absence of aggressiveness on the part of the disease, the absence of previous illness, or of focus whence tuberculization might be set up; and, lastly, because in one case recovery easily and rapidly occurred."

One of the pioneers in the use of the ophthalmoscope in nervous disease, T. Clifford Allbutt, of London,[1] long ago reported a series of equally instructive cases, but of a more severe type, in some instances the diagnosis being verified post mortem. He maintains that when a patient is seized with vomiting, headache, convulsions, and other symptoms of much meningitis, and when, at the same time, examination with the ophthalmoscope reveals congestion of the optic disks and retinal vessels, it can be said without hesitation that there is meningitis at the base of the brain. When, however, occasionally "purposeless" vomiting without nausea occurs, in conjunction with headache, fever, restlessness at night, spasmodic twitching during sleep, or even convulsions, with a change in disposition and slight mental impairment, together with the same ophthalmoscopic picture, and eventual recovery, "is it not probable that in these cases we have also meningitis—a meningitis less severe than that which proves fatal, but meningitis nevertheless?"

Bramwell[2] expresses the view that in some cases in which the onset is more or less sudden, and symptoms common both to meningitis and tumor—headache, vomiting, vertigo, optic neuritis, etc.—are developed, the headache and other symptoms disappear, the optic neuritis completely subsides, and the recovery may be perfect. . . . The lesion is more probably meningitis (syphilitic often) than tumor, or it may have been a gumma.

Other tumors may be excluded, for all pathologists know how rare it is to find within the skull the remains of a cured tumor other than a syphilitic gumma.

In the discussion upon double optic neuritis, before the Ophthalmological Society of the United Kingdom,[3] Hughlings Jackson differs from the foregoing opinion, and says that in cases of recovery from acute illness, where defective sight and some atrophy of the optic disks has remained, the evidence is in favor of gross local organic disease, such as tumor, rather than meningitis.

Complete recovery with good sight does not negative persisting local gross organic disease within the cranium. This is strikingly true in some cases of syphilitic tumor. Under treatment the symptoms pass off, though the patient may come again and again for the same localizing symptoms that indicate the persistence of the disease in one place. The fact of recovery is strong evidence against meningitis. And the question is asked, Have traces of meningitis been found after such recoveries, when the patients have died of some other disease?

This question can be satisfactorily answered in the affirmative by the history of a case, with autopsy, reported by Professor Haab, of Zurich, through whose kindness I am enabled to present the following notes:[4]

Louise S——, thirty years of age, consulted Professor Haab on July 17, 1882, and gave the following history: During the last six months she noticed diminution in visual power. Within the last four weeks her sight has been rapidly failing. Previously she was occasionally troubled with slight afternoon headache, but during the last two years the attacks of headache have been quite frequent. With the onset of severe headache the eyes became more prominent, but cardiac palpitation was never experienced.

She formerly received treatment for headache and gastric catarrh. Last winter she had tinnitus affecting right ear, and attacks of earache.

The headache is always worse on right side, and the pain reaches its maximal intensity at about 10 P.M., but is much less after sleep.

About four weeks ago she vomited a number of times during the same day. No attacks since.

Menses regular every three weeks. Father died of apoplexy. Mother has ascites. No tuberculosis in family.

Status præsens.—Fairly good-looking, middle-sized person. The eyes are somewhat divergent when she looks in the distance. Pupils equal and moderately dilated. The eyeballs are markedly prominent, so that when she looks directly before her a broad strip of the sclera is exposed, about two to three mm. above the corneæ. V. R.= movement of hand at 1 mm. L. = movement of hand at 50 ctm.

Ophthalmoscopic examination.—Media clear. The contour of optic nerves is obliterated, and papillæ enlarged, particularly the nasal halves.

Left.—The temporal half is white and atrophic.

Right.—The same is quite marked, but less than in left. Both disks show decided neuritis, the left somewhat older than the right, as indicated by the atrophy. The nasal half of right is redder, and when seen in the upright image has more fine capillaries than the left nasal half. A number of small vessels, which present a peculiar serpentine appearance, have formed over the left papilla. Upon both sides, left more than right, the veins are markedly full and rise above the level of the retina. No hemorrhages or changes in the macula region. No white spots in the retinæ. The nasal halves of papillæ are much swollen, so that the fundus measures H_2.D., while at the highest point of the nerve H_4.D. exists. Pulse, 100, and regular. Upon the right side of neck there is a moderate-sized struma which extends upward as far as the hyoid bone. This oblong growth is about the size of a hen's egg, and is often painful, whereas the left half of the thyroid is less enlarged and not painful.

Patient says that for a long time she has used ointment for her goitre, as it is a family complaint. Her father and grandfather had enlarged necks. Hearing normal on both sides. Urine turbid, slightly acid. No albumin.

Treatment.—Quinine muriat., 0.05, iodide of potassium, 0.1. Two powders daily. Smoked glasses.

July 25th.—When she looks down, the upper eyelids follow normally. She is hoarse to-day, as is often the case. During the last few days had constant very severe headache, less at night than during the day, but can only sleep an hour at a time. Dreams. V. R. = fingers at 1 foot, movement of hand at 10–12 foot. L. = momentary movement of hand at 1 foot with temporal part of retina.

Visual field: L. = marked contraction on all sides. R. = especially from inward, and also in the remaining radii. *Colors:* L. = none recognized. R. = only red, in pieces of four ctm. square at half foot. Blue and green not recognized. Pupils equal. Both dilated ad maximum. Ophthalmoscopically unchanged. No hemorrhages or foci of degeneration.

September 4th.—Her brother states that patient's sight has been failing, that the headache is increasing, and her appetite is bad. The urine contains some albumin. Upon the recommendation of Professor Haab she was admitted to the hospital, where she remained twenty-two weeks. Upon her return home she was quite well, had very slight or no more headache, and no vomiting. With the exception of the total blindness, she was in good health.

Her fatal illness began on April 1, 1883, with vomiting and diarrhœa. On the 2d, severe gastro-intestinal

[1] The Ophthalmoscope in Dis. Nerv. Syst. p. 88. 1871.

[3] Trans., vol. i., p. 73.
[4] Studien über den Zusammenhang von intracraniellen Affectionen und Nervenerkrankung. Inaug. Dissert., J. Zellweger. Zurich, 1887.

catarrh, with frequent vomiting, came on. On the 4th, symptoms of collapse appeared from constant vomiting. Abdomen tympanitic. No fever. Pulse, normal. At the same time her mother, who slept in the same bed, became ill with vomiting and diarrhœa. Patient's mind remained clear to the last. Anxiety and fear were the principal symptoms of which she complained. She died at 8 P.M. on the 5th of April.

The autopsy could not be made until the 8th. Permission was obtained with great difficulty, and with the understanding that only certain portions of the body should be examined. The following was noted by Professor Haab, who made the examination in the presence of the attending physicians:

Body not emaciated. Rigor mortis absent. Suggillations on upper part of thorax. The dura is firmly adherent to the calvaria, nevertheless it can be easily separated from it. The blood-vessels of the dura and pia are very full.

A few Pacchionian bodies are present. There is no flattening of the convolutions either at the convexity or base. The surface of the brain presents no abnormality in size or shape. Upon the outer side of the left frontal lobe, anterior to the pre-central convolution, over a number of sulci, the pia is milky and turbid in appearance. The subarachnoid space contains serous fluid which is somewhat yellow. Also in the right Sylvian fissure and in a few of the surrounding sulci there is turbidity of the pia and arachnoid, and a small collection of clear, non-purulent, yellowish fluid (hydrops meningeus). The same, in lesser degree, on left side. Over the chiasm and infundibulum, extending to the pons, are found numerous thin, connective-tissue like, newly formed membranes, which are firmly adherent to the pia. These membranes are densest directly over the chiasm, which is completely enveloped by them. Here the pia is also thickened and opaque. No sign of purulent exudation; no tubercle. The entire brain is richly supplied with blood. The brain substance is of normal consistency. No further abnormalities are discovered. No tumor. Motor oculi nerves normal. The optic nerves between the chiasm and optic foramen are somewhat flatter than normal. In the intra-orbital course of the optic nerves there is nothing remarkable macroscopically, except the atrophy, so that the nerves hang loosely in the canal. It was necessary to divide the nerves at the globe, as the removal of the eye-ball was not permitted. In the abdomen there was about five hundred c.c. of clear bloody serum. The serous coat of the small intestine was rose-red in color. No evidence of exudation. Kidneys small, surface smooth, capsule non-adherent. Cortical substance not swollen, and from gross appearance evidently not diminished. The liver shows signs of passive congestion (nutmeg type), otherwise normal. Spleen large, vascular, and tough. The stomach and intestines were not examined. Thoracic cavity not opened. Anatomical diagnosis, chronic basal meningitis of a slight degree. Atrophy of the optic nerves following neuritis.

In a subsequent review of the case the reporter says: "The changes in the optic nerves were undoubtedly due to the basal meningitis. (We could not learn anything further regarding the etiology.) Although the meningitic exudation completely enveloped the chiasm, the amount was nevertheless too small to have produced sufficient pressure that would lead to atrophy; neither did the floor of the dilated third ventricle press upon the chiasm. There was no evidence of a tubercular diathesis. No tubercles were found in the spleen or kidneys. Not the slightest trace of syphilis could be discovered. Microscopically there were no signs of endarteritis. Why the process should principally attack the neighborhood of the chiasm remains unexplained. As headache existed for two years before disturbance of vision led the patient to seek medical advice, it cannot be assumed that the optic nerves were primarily affected." A carefully written and detailed description of the microscopical examination is added, with the following conclusions: "The changes in the optic nerves may be thus summarized: Well-marked œdema of both optic nerve-sheaths; perineuritis; interstitial and parenchymatous neuritis, as a result of an inflammatory process occurring in the neighborhood of the optic chiasm."

The correctness of the diagnosis in my case is strengthened in the light of the foregoing contribution of Haab, this being the only case on record, with post-mortem verification, that I can discover, which in its main features bears a close resemblance to that which has served as a text for this paper. The principal points of similarity are: 1, The obscure etiology; 2, the absence of tubercular or syphilitic history; 3, the presence of headache, vomiting, tinnitus, and double optic neuritis; 4, the recovery (?) of the patient.

The question may now be asked, "Can we seriously entertain the diagnosis of brain tumor when headache, vomiting, and double optic neuritis are the only symptoms, in the absence of any evidence of syphilis, or tuberculosis, or other known cause of such a condition?"

In the present state of our knowledge it would seem that only by a careful process of exclusion, and by watching the progress of the case, is it possible to arrive at any satisfactory conclusion.

The literature bearing directly upon double optic neuritis from circumscribed basal meningitis is meagre in the extreme, and the subject is but rarely referred to in the text-books.

England is the prolific centre from which emanates the larger part of neuro-ophthalmological contributions of this nature. Clifford Allbutt, Hughlings Jackson, Hutchinson, Gowers, and others, have all made investigations along this line that are of lasting value.

The clinical importance of ophthalmoscopic examination appeals at once to every thoughtful mind. Without a view of the fundus of the eye, neurological investigation must remain incomplete and unsatisfactory. The ophthalmoscope brings to light, in many instances, the cause of obscure symptoms, and thus makes a rational course of treatment possible. The presence or absence of optic neuritis should be determined in every case. It is the neurologist's province to detect or exclude such morbid processes, overcome or arrest them when possible, and recognize their significance at all times. The ophthalmic surgeon in but few instances is called upon, unless failing sight or other subjective eye-symptoms are complained of, at which stage post-neuritic atrophy may be advancing and blindness imminent.

Unfortunately, good evidence of probably organic intracranial disease may be lost, as many cases of optic neuritis pass unrecognized for the following reasons:

1. As the patient does not complain of the eyes.
2. Owing to the absence of ocular symptoms.
3. Because, when the patient is able to read the standard test-type at the normal distance, the presence of optic neuritis is excluded.
4. As many physicians of intelligence and experience still harbor the idea that the existence of optic neuritis implies either blindness or decided deterioration of vision.
5. Because the ophthalmoscope is not in routine use.

Hence the frequency of avoidable errors in diagnosis which have at times been exemplified, for instance, in cases of persistent vomiting, where the stomach had been "washed out" for a prolonged period before the only symptom of cerebral disease was discovered upon ophthalmoscopic examination. (In young children it is often necessary to dilate the pupils with cocaine or atropine before a satisfactory view of the fundus can be obtained.)

Double optic neuritis is a serious condition, not only as a distant or indirect manifestation of intracranial disease, but also in the probability of its resulting in blindness. Dr. Jackson [1] calls attention to the fact that a patient with optic neuritis and other non-localizing symp-

[1] Transactions Ophthalmological Society, United Kingdom, vol. i., p. 75.

toms, may die rapidly or suddenly of the brain disease which they signify.

There are numerous instances on record where the patients have recovered with normal or useful vision; but there are many more, and I think they are in the majority, where the neuritis terminates in blindness. The same writer[1] very aptly says: "There would be fewer blind people if the ophthalmoscope were used in some so-called bilious attacks, in some so-called cases of hysteria," etc.

With so many expert oculists among us, who are ever ready to advance the cause of science, humanity, and knowledge, it should be impossible for those who complain of headache and vomiting of doubtful or obscure origin, to escape investigation as to the condition of the ocular fundus.

It is to be deplored that the studies of ophthalmology and neurology are not more closely associated. The two specialties are to a great extent interdependent. The practical advantages of this association must be evident to all. Such a combination would always enhance the value of clinical observation. No further emphasis or illustration is required to enforce this impression. In order to more firmly establish this relation, every eye infirmary should include in its service a separate department for nervous diseases. Many years ago the Manhattan Eye and Ear Hospital adopted this plan, and it is still in successful operation.

If this paper succeeds in directing the attention of the profession to a type of cases not universally recognized, and serves as a stimulus to encourage, cultivate, and sustain a bond of union between the ophthalmic surgeon and the neurologist, the objects of the writer will be accomplished.

ON THE HEALTH-VALUE TO MAN OF THE SO-CALLED DIVINELY BENEFICENT GIFT, TOBACCO.

By J. M. W. KITCHEN, M.D.,

NEW YORK.

With perhaps the exception of heredity, the question of stimulants and narcotics in their relation to the physical welfare of the race is second to none in importance. With trifling exceptions, the whole world is addicted to their use. The universality of such use has led many to consider them a necessity to man, and that they are God's gifts to him, and, if rightly used, are of physical benefit. It may not be a perversion of judgment to consider that their wide-spread popular use is greatly due to the efforts of the race to gain anæsthesia for, and distraction from, those pains and punishments that are the inevitable sequence of departure from hygienic and social law on the part of the individual, his ancestry, and society in general.

The taste for these things is acquired, not natural, though the acquisition may be through hereditary influence. An idea is held by a majority of even fairly intelligent individuals that there is a justifiable, harmless, and even beneficial use of these substances by the general public, though acknowledging that beyond a certain indefinite line this use becomes an abuse.

I believe that there may occasionally be cases in which the physical benefits derived from their use outweigh the injury they inflict, but I think this use is very much less than is generally supposed, and if we can judge from the preponderance of evil effected by such use, these substances ought to be considered as the materialized curses of God rather than as beneficent gifts. The prevalent idea as to the beneficent nature of these substances I consider to be a delusion that can only be explained upon the hypothesis that there is a wide-spread lack of appreciation of the fact that, though they may have an immediate pleasant and agreeable effect upon the body, their injurious effects are cumulative, and are usually ultimate, and so distant as to be difficult of direct connection with their cause to ordinary observation. The more moderate the use of these substances the more remotely is the effect removed from the cause and more difficult of detection. That the ordinary habitual, so-called moderate use of stimulants and narcotics such as tea, coffee, tobacco, and alcohol is, in the vast majority of cases, really an abuse is a proposition that I think should be admitted by all who have given the subject an unbiased study.

The idea that the user of tobacco and other injurious substances will be cognizant of the injury inflicted by habitual use in moderate or even excessive amounts is an undoubted fallacy. The daily, weekly, or monthly injurious effect may be entirely unobservable to even trained physicians, and yet the ultimate cumulative effect may be fatal. I can instance numerous cases of physicians directly fatally injured by the use of alcohol, who have never had the slightest cognizance of the fact; and I can also instance cases of grave disease from the use of tobacco where the patients never have believed that tobacco has been the cause of their troubles, even after an unanimous opinion to that effect has been expressed by a number of competent medical advisers. The habitual consumption of opium, in doses of any amount, is generally admitted by most people to be physically injurious outside of its strict medicinal application. Moderate indulgence in alcohol as a beverage is beginning to acquire a very wide-spread evil reputation. But how about tobacco? Tea and coffee we can confidently leave to the consideration of a somewhat remote posterity of a considerably advanced intelligence and elevated hygienic ideals.

The relation of tobacco to the physical welfare of man can only be fairly estimated by viewing the subject in its broadest aspect; by considering its effects upon the race as a whole rather than in individual cases; by taking into consideration economical and other social conditions that at first sight might be considered as having little relevancy to the medical side of the subject. But there can be no just consideration of the matter otherwise. The direct deleterious effects of the immoderate use of tobacco are readily observable; but the great bulk of the evil physical effects due to the moderate use of this plant are of an intermediate nature and not directly noticeable; nevertheless, they are real, and worthy of medical attention. The plainly marked results following the use of tobacco in relatively large amounts seem to be due to quick and extreme interference with nutrition, and a diminution of function of all kinds, which may be represented by anything from a slight decrease of appetite and digestive ability up to a complete loss of function of almost any important organ. Tobacco has stimulating as well as narcotic properties, but, as ordinarily used, its stimulating effect appears to be slight as compared with its narcotic influence. In this respect it differs from alcohol, the use of which, owing to the usual method of introduction in large amounts through the stomach, produces directly, by stimulation, readily noticeable structural changes. But with tobacco the direct evil results are mostly of a functional character, and are more generally diffused, owing to the usual slow manner of introduction into the body. These two properties have an effect upon the body in moderate use as well as in immoderate use, the effect being simply in proportion to the quantity used, though the effects of moderate use may not be measurable by ordinary means. It is easy to see the effects of large amounts of tobacco in the stunted growth of adolescents; in functional cardiac disorders; in intellectual sluggishness, loss of memory, and color-blindness; in loss of appetite, and other neuroses of motion, and marked blunting of various functions of sensation, and in degeneracy of descendants; but that lesser evils are produced must be proved mostly by inference, circumstantial collateral evidence, and analogy.

The greater evils that are the outcome of a moderate use of tobacco are probably due to prolonged slight interference with nutrition, and consequent general decrease of vitality which renders the individual more susceptible

[1] Ibid., p. 93.

through indirect influence to the invasion of disease, and which lessens the capacity for productive effort.

It is of course difficult, and perhaps even impossible, to accurately estimate the value of tobacco to the race; but let us glance at the pros and cons, and then each one can roughly estimate for himself. Tobacco may be used medicinally, but it is a dangerous and uncertain remedy, and it probably has not one medicinal use that cannot be more suitably met by other remedies. One can readily imagine easier digestion as the result of the sedative influence of the after-dinner cigar upon a disquieted nervous system, especially if the coincident irritation of alcohol and coffee have need of correction; but it can also be imagined that in most of such cases the remedy has been the cause of, and will further increase the disordered condition, and that nutrition of deficiently nourished nerve-tissue is rationally indicated rather than partial narcotization. There then remains, so far as I can see, the solace of moderate anæsthesia and, occasionally, of occupation for idlers, as the only items that can be placed to the credit of tobacco. There certainly are individual cases where such usage may be more provocative of physical benefit than evil, but, before judging for the race as a whole, compute the other side of the question.

Tobacco injures the general health of the public through the economic loss caused by its consumption. The people of our country spend annually over seven hundred millions of dollars for tobacco—twenty per cent. more than is spent for bread. This sum represents only a minor part of the cost of the toabcco-habit to the country. The crop is immensely exhaustive to the soil. Its culture has blighted whole sections of fertile territory. In the time consumed by the producer and the trader in its production, manufacture, and sale, and by the consumer in its use, and by the general interference with vital activity and consequent decreased productive capacity, there is represented an almost unimaginable sum of money. Certainly the people at large are not so well fed both as to quantity and quality, or so thoroughly clothed, or so hygienically housed that they can afford this gigantic economic waste.

There can be little doubt that if the people had sufficient intelligence and moral strength to taboo tobacco, this comparatively senseless outgo would be largely devoted to supplying these and other necessities of an exalted health-status.

Tobacco injures health through its moral effects. The tobacco-habit is certainly a dirty, and frequently a disgusting habit, and encourages other dirty practices. Its use tends to make men cowardly, irritable in temper, and low in spirits. It blunts ideas of purity and courtesy, leading to invasion of the rights of others. It is presumed that few medical men would visit a delicate, sensitive patient after saturation with the "fragrant" effluvia of onions, but thousands whose systems are saturated with nicotine and who reek with nauseating odor do not hesitate to inflict their presence on sick or well. The time will come when the tobacco-user will not be allowed to poison the atmosphere that is the common property of the public—will not be allowed to force the inhalation of nicotine upon the general public, to say nothing of being allowed to poison the infants and women in his own family. What would be said of a man who introduced poison in any degree into the food or drink of his child? Is the poisoning of the household atmosphere by the ignorant, thoughtless, or selfish smoker morally more defensible? Tobacco injures health through hereditary influence The tobacco-user begets, more certainly than the non-user, puny children with disordered nervous conditions. Luckily for our race the women, who have the most important prenatal influence in guarding its physical well-being, are practically non-users of the plant. The general health-status of the race is improving, not because the use of tobacco or the indulgence in other questionable practices is harmless, but because, among other things, of the great advance in general intelligence and knowledge of hygienic law.

A person, or the public in general, may practise an injurious habit, and yet more than counteract its influence by opposing beneficial practices.

Horace Greeley said, "Show me a drunkard who does not use tobacco, and I will show you a white blackbird." In this country, where dietetic drinking habits are not common in the family, the weakening of moral fibre by indulgence in tobacco is usually the introduction into the round of vicious indulgences, and thus directly or indirectly affects health. Smoking induces dryness of the mucous membrane of the mouth and consequent thirst. The partially paralyzed nerve-terminals want something more stimulating than water to afford relief. Furthermore, blunted appetite induces deficient nutrition, and consequently there is a call for some "pick-me-up;" hence we find that the use of tobacco tends to the habitual use of alcoholic beverages, and there are very few habitual users of alcohol who escape without structural injuries to the body as well as perversion of its functions. Decrease of vital activity in all the tissues of the body marks the use of tobacco. The tendency is toward functional paralysis, though occasional signs of stimulative irritation are to be noticed, especially in the respiratory passages. The interference with intellectual activity is marked. It is said that during a period of fifty years no tobacco-user stood at the head of his class in Harvard. The accumulated testimony of investigating observers is conclusive that, other things being equal, users of tobacco, in schools of all grades, never do so well in their studies as non-users.

One head of a public school said he could always tell when a boy commenced to use tobacco by the record of his recitations. Professor Oliver, of the Annapolis Academy, said he could indicate the boy who used tobacco by his absolute inability to draw a clean, straight line. The deleterious effects of tobacco have become so clearly apparent that we find its sale to minors is prohibited in France, Germany, and various sections of this country. It is somewhat a question if, at the present time, the race is not doing itself more injury by its use of tobacco than it is with alcohol, because of its more universal use, particularly by youth, and because of the respectability of the habit which comes of its use by a certain intelligent part of the race, including teachers of morals and physics, and even temperance reformers. There is a wide-spread sentiment in existence that it is not a respectable thing to be even partly paralyzed by alcohol, but how few there are who consider narcosis as in any way connected with the use of tobacco. Its effect is more diffused and masked, and is not so acutely serious in individual cases, but through its interference with vital activity, tobacco is probably more generally injurious to the race than alcohol.

The editorial fiat of "too long" prevents a full exposition of the subject, but, in closing, let me say I hear millions of tobacco-users ask, "Why, then, was this plant given to man, if its general effects are so decidedly evil?" The question presupposes design in creation. Without subscribing to this theory, or pretending to have solved the mystery of the presence of evil in the world, the answer may be suggested that the overcoming of many seductive evils becomes to man a means of his progressive higher development. Of one thing I am convinced, that the physical development and welfare of man is interfered with in strict sequence to his consumption of substances that are unnecessary for his nutrition—stimulants and narcotics inclusive.

THE SALE OF PRACTICES.—The French courts have decided that a physician cannot legally sell his practice, on the ground that a medical practice is not an article of commerce. A contract to abstain from practising in any given neighborhood is, however, valid, and to be capable of enforcement at law.

Clinical Department.

AMPUTATION OF THE THIGH OF A THREE DAYS' OLD GIRL.

By J. W. MADDIN, Jr., M.D.,
NASHVILLE, TENN.

On Monday, March 11th, I was called to see a baby which had just been delivered by a midwife, the child of German parents; the father, a vigorous healthy man, a cooper by trade, and the mother, a large, muscular woman, weighing about two hundred and twenty-five pounds. Upon examining the child it was found that the right leg had been the seat of mortification, or dry gangrene, up to about the junction of the middle with the upper third of the thigh. From the knee down, the bones were bare of any covering, the foot was disarticulated from the leg, and seemed to be undeveloped, swarthy, mummified tissue. It was connected to the leg only by a few shreds of mortifying tissue.

I called Drs. T. L. and J. W. Maddin to see the case with me, and consult as to the best thing practicable to be done in such a case. It was at once decided that nothing but amputation was left to be done, but that the operation should not be performed till nature formed her line of demarcation, lest gangrene should attack the stump and make matters more complicated than they were already. At the end of three days there was an indistinct line of separation of the healthy from the gangrenous tissue, and the operation was resorted to immediately. The transfixion operation was the one selected, and was performed just below the hip-joint, making use of the anterior and posterior flaps, and it was with difficulty that enough healthy tissue to cover the wound was obtainable, so far up the thigh had the gangrene extended.

No tourniquet was used, but the bleeding was controlled by compressing the artery, where it passes over the pelvic bones, with the finger. The tissues were dissected back to within about an inch of the head of the femur, and the bone sawed into at this point. The operation was completed in the usual way, tying the arteries with silk ligatures and closing the wound by bringing the flaps together with silk sutures. No drainage was provided for, other than that caused by allowing the ligatures to pass out of the lower end of the wound. The wound healed very promptly, with but little suppuration or discharge; the dressings were renewed every two days, and at this writing, twenty days since the operation, there is only a small part of the wound not closed.

Ether was the anæsthetic used in this case, and was very skilfully administered by Dr. J. E. Harris, a very remarkable fact in connection with the anæsthetic being that nearly a half pound of Squibb's ether was used before sufficient anæsthesia was accomplished to proceed with the operation, and it required thirty minutes to accomplish this amount of anæsthesia.

The child rallied from the ether and the shock very promptly, and has had no bad symptoms since, except occasionally to refuse to take the breast, during which time it was nourished by breast-milk taken from a spoon.

I am indebted to Drs. J. L. Watkins and Henry Morris for able assistance in the operation.

At the present time the child presents every prospect of recovery, although at the time of the operation it was hardly hoped that a favorable result could be accomplished.

The only cause which I could assign for the condition of the leg at the time of its birth was the wrapping of the cord around the limb in the early months of intra-uterine life, or else to a fall which the mother sustained on Christmas day, being just eighty days before delivery. In this fall she struck the abdomen very forcibly on the ground.

This case is unique in the extreme early age at which the operation was performed (the child being only three days old), and in the fact that it required nearly a half pound of ether and thirty minutes of time to produce anæsthesia, which was never profound at any time.

MEMBRANOUS RHINITIS.

By ISIDOR GLUCK, M.D.,
OCULIST AND AURIST TO THE ACADEMY OF THE SACRED HEART AND BROWNELL HALL, OMAHA, NEB.

I venture to call attention to a disease concerning which little has been written, and apparently little known. The only publication I could find on any affection similar to the one here described is a paper by Frank Hamilton Potter, of Buffalo, N. Y., read before the State Medical Society of New York, February 5, 1889. The characteristic feature of the affection described in the above paper is the formation of a membrane with hardly any constitutional symptoms. The duration of the disease, notwithstanding the most energetic treatment, both constitutional and local, according to Dr. Potter, was about three weeks. The local treatment consisted in applying a solution of cocaine and tamponing the nose.

Membranous rhinitis is a term which designates an affection of the nasal passages, independent of diphtheria, manifested by an acute inflammation and by the formation of a membrane caused by exudation and covering a part of the turbinated bones. Generally both sides are affected at the same time.

The onset in a series of cases which I have observed was sudden, and simulated an attack of hay fever. There was great swelling and redness of the mucous membrane. On closer inspection of the nasal passage there could be seen a strip of white substance blocking up the space between the septum and upper and middle turbinated bones. The secretion of the nose was of a sticky, but clear, transparent character. There was no marked elevation of temperature. Patients complained of a tired feeling and general discomfort. No history of previous attacks of the same character, only susceptibility to colds, and in some cases to catarrhal affections of the nasal passages. When the membrane is seized with the intention of removing it, only the part seized tears loose. It appears to be a milky white, flat mass, with a large quantity of moisture on both sides. On removal there is left a bleeding surface, which I believe is not caused by the forcible separation of the membrane from its base, but rather from the contact of the instrument with the inflamed parts. On the next day the membrane is found reformed. The pharynx and larynx are not involved, excepting that the soft palate is relaxed and the uvula elongated.

The cases observed occurred in a succession of two years, during the months of April, May, and June. The patients applying for treatment had been suffering from a few days to as many weeks, some believing themselves to have a bad cold of an unusually long duration, others thinking of hay fever, although it was too early in the season. I first applied a four per cent. solution of cocaine in a very fine spray, avoiding the use of a coarse spray on account of its causing irritation and violent sneezing. Cocaine had very little effect in these cases. It loses its power of causing contraction of the tissues in proportion to the intensity of the inflammation present.

Assuming that the disease was local, and the membrane formed by exudation, I therefore ventured to try a drug, viz., atropine, which I knew from experience has a power of checking exudation, and on this I based the treatment.

Atropine applied locally accomplished all I expected. It acted as a local sedative, caused contraction, and checked exudation immediately.

A New Pun at the Paris Jockey Club: "Le malade prend l'avis du docteur et le docteur prend la vie du malade!"

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 27, 1889.

THE TREATMENT OF INEBRIETY IN THE EDUCATED CLASSES.

IT requires but little reflection to enable one to understand that the treatment of inebriety should be along very different lines according to the varying social conditions of the patient. This is true, indeed, of nearly all diseases the types of which often differ widely according to the surroundings of the patient, but of none is it more true than of nervous affections, and especially, perhaps, of inebriety. The inebriate who has been born and has passed all his life in the slums of a large city is very unlike, in both moral and physical constitution, the well-to-do gentleman, whose surroundings are the most refined, and who deplores his infirmity and shudders to think of the world of his associates becoming sharers in his secret.

The management of cases falling in the latter category is the subject of a communication read before the London Society for the Study of Inebriety, on January 1, 1889, by Mr. James Stewart. The author starts out with the assumption that in every inebriate there is an absolute degeneration of brain elements and that upon this depends the loss of will-function. This being admitted, the treatment should be so directed as to assist nature in her efforts to regenerate the injured nerve-tissue, to build up again the brain elements through the medium of which the will-power and other functions are exercised. In order to do this total abstention from alcohol is absolutely essential, and nothing containing alcohol, not even the lightest wine or beer, is to be permitted at any time even during the intervals of the drink-craving. The will of the patient being weakened, he must live under the constant supervision of the physician. For this purpose the author advises a residence in the country, in the home of some medical man. The latter should not be in active practice, but should be in a position to devote his entire time to the patients, not more than five or six, entrusted to his care. If there be a greater number of "guests" than this the domestic family feeling will be destroyed, and the inebriate will come to regard himself as in an asylum rather than a private house.

The life at the home is to be made as little irksome as possible, and amusements of various sorts should be provided. The patient, if he have no literary tastes or no hobby, such as painting, wood-carving, or the like, should be induced to take up something like photography which will consume much of his time and lead him out frequently into the open air. He should also be encouraged to take up pedestrianism, being accompanied in all his walks, of course, by the physician or his deputy, and should be taken frequently to public meetings, concerts, lectures, cricket-matches, and the like. The physician will be greatly aided by a pleasant and energetic wife, or other female members of the family, who may assist in the entertainment of the guest in the home circle during winter evenings and at other times. If the patient is a lady the help of the physician's wife is, of course, absolutely indispensable.

This is briefly the plan of treatment advocated by Mr. Stewart for the intelligent inebriate who is earnestly desirous of overcoming his infirmity and is willing to submit for a period of a year to a moderate degree of restraint, putting his will to a certain extent in the keeping of the physician. But, and especially at the beginning, something more is needed than mere occupation. It is necessary to moderate as far as possible the craving for drink, which returns with almost irresistible force at frequent intervals, and also to overcome the depression from which the inebriate is usually suffering when he first reaches the house. For the latter it will be necessary to administer, at intervals of an hour or two at first, egg and milk, beef-tea, milk and lime water, soda and milk, and other easily assimilated beverages. The sleeplessness from which almost all inebriates suffer at first is best treated by a draught composed of twenty minims of the solution of bimeconate of morphine with ten or fifteen grains of chloral, alternated for a few nights with other hypnotics. Sulfonal will doubtless be found very serviceable in such cases. The author protests against the idea that by the exhibition of drugs such as capsicum, perchloride of iron, or strychnine, the craving for alcohol may be destroyed or kept under. It may perhaps be smothered for a while, he says, but he believes that by this treatment the physician is only substituting one enslavement for another. The same is true to a certain extent in respect to aerated beverages. Without absolutely interdicting the latter he recommends his patients to do without them, and to drink plain water at their meals and take plenty of milk with either tea or coffee, or, as he prefers to either of the latter, cocoa. The diet should be plain and unstimulating and all condiments should be avoided at meals. If the patient suffer from pain in the stomach after the ingestion of food he should take large draughts of very hot water twice or three times a day. Smoking should be reduced if it cannot be entirely given up.

The author summarizes his conclusions, which he has arrived at as the result of constant clinical study during the last twelve years, as follows:

1. Drunkenness and inebriety ought not to be confounded.

2. Inebriety is a lesion of the brain which has gone so far as to affect the will-power.

3. Successful treatment based on this pathological dictum must include the absolute cessation of alcoholic drinking.

4. There is no danger in the sudden and complete withdrawal of alcohol if the case—no matter how severe—be in the hands of a skilful physician able to personally direct the hourly treatment from the first.

5. The physician undertaking the charge of such cases

ought to be a total abstainer, as well as everyone living under his roof, so that moral treatment by example may supplement therapeutic remedies.

6. Permanent recovery need not be hoped for unless both lines of treatment be pursued, systematically, during an uninterrupted period of twelve months in a "Home" from which every beverage containing the smallest quantity of alcohol is absolutely excluded. The first four months barely suffice for the getting rid of the stomach and other troubles which are the result of the alcoholic poison; at the end of the second period of four months the patient begins to feel less the want of alcohol; by the end of the third period he has begun perhaps to understand that life may be enjoyed and vigorous health secured without stimulants.

7. So-called "cures" effected by bark, strychnine, iron, and other drugs have not proved permanent.

8. The permanence of a cure depends greatly on the after-treatment pursued subsequently to the patient leaving the "Home." The family of the inebriate, or the household of which he or she is to form a part, ought all to become total abstainers, no alcohol being allowed under any circumstances into the house except as a drug prescribed by a medical man and dispensed in a medicine bottle.

THE PRESENT ASPECT OF THE IODOFORM QUESTION.

The triumphant march of the germ theory received some four years ago an unexpected and, it seemed at the time, a final check. Just when it seemed to have been surely determined that unhealthy action in wounds was caused directly by the entrance of disease germs from without, and that the exclusion and destruction of germs would secure rapid and normal repair, the startling discovery was made that iodoform, which was widely used as an antiseptic, and which evidently promoted greatly the healthfulness and healing of wounds, was not a germicide, and might in fact be the vehicle in which germs were carried into the wound. In an article in the *Annals of Surgery*, March, 1889, Dr. Van Arsdale discusses the matter fully, showing what interesting discoveries have resulted from the refusal of iodoform to fit into the old theory, and giving the literature of the subject.

Investigation has proved that disease germs are aided in their septic work by certain chemical substances called ptomaïnes, which are formed in the tissues as a result of their action upon the tissues. Iodoform, while it does not destroy nor seriously hinder the germs, does destroy the ptomaïnes. Thus, we may suppose, the tissues, not being enfeebled by the action of the ptomaïnes, are enabled either to destroy the germs or to resist their malign assaults.

Clinically, certain facts have been developed which are of practical value, whatever may be the fate of the scientific theories involved. In dressing wounds the surgeon must hereafter use two different sets of antiseptics. He must first seek, as far as possible, to exclude disease germs or to render them inactive, and for this purpose he must use germicides, such as corrosive sublimate. He must next endeavor, by applying agents like iodoform, to prevent the formation of poisonous chemical substances in the wound, or to decompose them and render them inactive if once they have been formed. These latter agents, if they, like iodoform, contain disease germs, must be disinfected before they are applied. Iodoform should be washed in corrosive sublimate solution. It should be brought into as intimate contact as possible with the surface of the wound, and after its application the wound should be covered with germicide and protective dressings.

NOTES ON THE USE OF PARALDEHYDE.

In an article upon the treatment of mental diseases (*American Journal of the Medical Sciences*, April, 1889) Dr. Clouston, of Edinburgh, gives his experience with paraldehyde. For two years he has used it very extensively and he likes it far better than any other pure hypnotic. Very often the patient is asleep in five minutes after the drug is given. In one hundred cases it caused sickness in only two, headache and disagreeable feelings in one, and a "general discomfort" in one. It does not interfere with the appetite for food next morning, nor disturb the stomach or bowels. He believes that while the first part of the sleep given by paraldehyde is a drug sleep, the rest of the sleep is natural sleep. In some cases it restores to the brain the habit of sleep, and it may be discontinued without danger of relapse into old ways, and without leaving a drug habit. It is of no use, but rather injurious, when given in the day-time. The dose varies enormously according to the case. Too small doses may excite the patient. He begins with one drachm or forty minims and goes up to two drachms in ordinary cases. In very many cases of confirmed insomnia, in melancholia, and in acute mania, three, or even four drachms are required. He has given to one patient, four drachms every night for a fortnight. He gives it in tincture of quillaya, with a few drops of chloral ether, in cinnamon water. Its bad taste cannot be concealed and patients smell of it for twenty-four hours after a dose. In what dose it becomes poisonous is uncertain. A nurse gave an ounce to a delicate patient, producing stertorous sleep for twelve hours, but no interference with the heart's action or the reflexes. The patient recovered. Because of its volatile nature it is quickly eliminated by the lungs and also by the kidneys. In cases of mania he often adds a drachm of one of the bromides to the evening dose of paraldehyde, and in very restless cases a drachm of "bromide." He thinks he has never injured a patient nor retarded recovery by even a prolonged use of paraldehyde.

CONTINENCE AS A PREVENTIVE OF SYPHILIS.

In closing his remarkable series of lectures on "Syphilis of the Nervous System," Dr. William R. Gowers, one of the foremost of English neurologists, makes these very vigorous statements:

"Do we do all we can—and our profession gives us power that no other has—do we do all we can to promote that perfect chastity which alone can save from this, and from that which is worse? The opinions that on pseudo-physiological grounds suggest or permit unchastity are absolutely false. Trace them to their ultimate basis and they are groundless. They rest only on sensory illusions, and 'there are no liars like our own sensations.' Rather, I should say, they rest on misinterpretations, always biassed and often deliberate. With all the force that any knowledge I possess can give, and with any authority I may have, I assert—as a result of long observation and consideration of facts of every kind—that no man was ever yet the slightest degree

better for incontinence; that for it every man must be the worse morally, and that most are worse physically; and in no small number the result is, and ever will be, utter physical shipwreck on one of the many rocks, sharp, jagged-edged, or on one of the many banks of festering slime that are about his course, and which no care can possibly avoid. And I am further sure that no man was ever anything but the better for perfect continence. My warning is: Let us beware lest we give even a silent sanction to that against which I am sure, on even the lowest grounds that we can take, we should resolutely set our face and raise our voice."

It is at least impressive and refreshing to hear convictions so positively and eloquently expressed upon this subject. The tendency, we know, in these days of physiology and material hygiene, is to excuse or even permit incontinence in man, on the ground of its physical necessity. A great deal of so-called physiological craving comes, however, from systematic cultivation of or indulgence in lewd emotions, when a systematic repression of the animal instinct and cultivation of faculties that distinguish man would produce a very different condition in the sexual instincts.

THE RESPIRATION OF WOMAN.

Some two years ago Dr. Thomas J. Mays, of Philadelphia, studied the type of respiration in eighty-two North American Indian girls, varying in age from ten to twenty-two years. He found that the abdominal type of breathing was very marked in every case and came to the conclusion that the costal type usually observed in civilized woman was artificial, and the result of modern dress.

Dr. J. H. Kellogg, following up the same line of inquiry, has since then examined the mode of respiration in several Chinese women, whose dress does not constrict the waist, and in Indian women. He found also that they showed the abdominal type of breathing. He also found in a number of cases that civilized women who wore no corsets had relatively good abdominal breathing, and that this was prevented when they put on a corset. He also produced a costal type of breathing in man by putting him in a corset.

Dr. Kellogg's conclusions are also to the effect that the so-called costal type of breathing is an artificial and injurious one. He also found, by means of specially constructed instruments, that the respiratory movements produced certain movements of the pelvic viscera, more especially the uterus, and that these movements were lessened by the constriction of the corset. He found, however, that the uterus was lowered in the pelvis from .2 to .5 of an inch by the application of the corset. He states, what anatomists have long known, that the round ligaments contain muscular fibres; but he adds that they tend to contract with the respiratory movements, raising the uterus up, while the abdominal viscera press it down. By the wearing of corsets these muscles fall into disuse, atrophy, and their function is lost.

The facts above presented are apparently very strongly in favor of the artificiality and, by inference, harmfulness of the costal type of breathing. But it must be remembered that Hutchinson found this type marked in twenty-four girls, of ages varying from eleven to fourteen years, who had never wore tight clothing around the waist. Gibson states that the differences in types of breathing begin as early as the tenth year; while Riegel asserts much the same thing.

There seems to be considerable reason to believe, therefore, that the costal type of breathing has at least become established in civilized women; and it has not yet been proved that it has an injurious influence. The harm done by tight lacing is admitted, but it may be questioned whether the costal breathing is not even an improvement on the abdominal type.

A NEW INTERNATIONAL MEDICAL CONGRESS.

The medical profession of the world will wake up in a few weeks to the fact that their Parisian colleagues are quietly organizing an independent International Medical Congress, to be held in Paris during the coming Exposition. Nearly every week a new announcement of meetings of medical organizations having an international character is received. Among the latest are the Congrès International d'Assistance Publique, and the International Congress of Therapeutics and Materia Medica. The former organization meets on July 28th, under the presidency of M. Roussel. It will consider questions of the management of hospitals and of the care of defective and dependent classes. The Congress of Therapeutics meets the same week, August 1st to 5th.

VACCINATION AGAIN.

We can hardly understand the extreme solicitude our English medical contemporaries always feel over the subject of vaccination. Any attack upon, or criticism of, this time-honored mode of prophylaxis arouses at once an elaborate procession of statistical editorials and vaccinal apologetics. One can appreciate and allow for a reasonable irritability over the silly discussions of Miss Frances Power Cobb and writers of that class.

But an equally extreme degree of agitation has been shown over the contribution to vaccination somewhat recently made by Dr. Charles Creighton in the last volume of the "Encyclopædia Britannica." This is an article written in what appears to us to be an independent and critical spirit; and his chief fault, as will be seen, is that he has only studied thoroughly one part of his subject.

The writer does not take an anti-vaccinationist's standpoint exactly, but rather seems desirous of showing that the facts of the work of vaccination should be interpreted in the light of modern epidemiology, as well as of vaccination prophylaxis. All great plagues have had their rise and decline, and small pox is no exception. Dr. Creighton attacks also, very sharply, the Jennerian theory of cow-pox, viz., that it is small-pox in the cow, and is derived from the equine disease known as "grease." There is, according to Creighton, no identity, or even affinity, between these diseases, and, in fact, all the theories of vaccination he seems to regard as fanciful.

The practical value of small-pox, apart from any theory, is considered separately. Taking the question of its prevalence in general, Creighton inclines, as we have stated, to believe that its diminished activity is due to epidemiological laws rather than to cow-pocking. As regards individual prophylaxis he brings forward rather meagre statistics, but admits a somewhat greater prevalence and virulence among the unvaccinated.

On the whole, one is inclined to regret that Dr. Creighton, having started out to present his independent views, did not take time and space and material sufficient to defend them. The sections of his article on the practical value of vaccination are disappointing, viewed from a purely objective stand-point; while his reference to the work of Jenner is lacking in candor, if not actually in knowledge.

In very marked contrast to Dr. Creighton's article is the one on the same subject by Dr. Samuel W. Abbott, in the recently issued volume of "Wood's Reference Handbook of the Medical Sciences." The discussion of the protective value of vaccination is here entered upon most exhaustively, and there are plenty of data opposing Dr. Creighton's epidemiological theory.

We have not space nor inclination to introduce the details of a pro-vaccination argument here. Vaccination has cut down small-pox too rapidly for it to be explained by a natural law of decline. It is a measure of prophylaxis which every intelligent man who studies the question without bias must admit is most potent and beneficent.

The anti-vaccinationists may have some actual influence in England, to us they appear to be simply the victims of hysterical rhetoric and statistical hallucinations.

THE PROMOTION OF WEEKLY REPOSE.

THE season of the year is approaching when church attendance declines and the carnival of Sunday excursions begins. No city in the world works harder to get what it thinks is rest and recreation on Sunday than New York. Cut off on three sides from the mainland, nearly all the objective points sought for by the Sunday excursionist are reached by ferries or boats, the trips generally involving a ride on an elevated road, the crossing a ferry, and a railroad trip, with, perhaps, a stage drive at the end. No resting-place can be reached short of an hour or an hour and a half of hard travel, generally in crowded conveyances. The result is that the Sunday excursionist toils so much for his rest that the total result is a decidedly negative one.

A society for promoting weekly repose in New York city during the summer would find large opportunities for its labors.

The recent organization of an International Congress for Weekly Rest, to be held in Paris during the coming Exposition, is suggestive in this connection, and we trust that it will have some New York delegates.

THE PRACTICAL STUDY OF THE INTESTINAL JUICES.

IN a preliminary communication to the *Centralblatt für Klinische Medicin*, No. 6, 1889, Dr. J. Boas, of Berlin, states that by certain manœuvres he has been able systematically to obtain the intestinal juice in living patients for purposes of study. By intestinal juice he means a mixture of the pancreatic juice, the bile, and the succus entericus.

His method is, after the stomach digestion has ceased and that organ is empty, to rub the abdomen from the region of the right hypochondrium toward the median line. This gradually relaxes the pyloric sphincter, and after a time the intestinal juices enter the stomach in considerable amount. These are withdrawn with the stomach-pump. In twenty cases the amount of secretion thus obtained has been from 15 to 200 c.c., the average being 40 to 50 c.c. The fluid withdrawn is feebly alkaline and possesses all the properties of the intestinal juices, viz., it digests proteids, turns starch to dextrine and maltose, and emulsifies fat.

In case a mixture with gastric juice is apprehended, the stomach may be first washed out with a weak alkaline solution.

Dr. Boas is confident that in his new procedure we have an additional means of examining the condition of the digestive tract and securing more positive data for the treatment of its disorders.

It is somewhat to be regretted that in his present communication he does not give us more details of the procedure which he employs. These will, we are told, be furnished later.

REGULATION OF MEDICAL PRACTICE IN PENNSYLVANIA.

THE State of Pennsylvania is in the throes of medical legislation. The bill now before the Legislature to establish a board of medical examiners has been amended until, at last accounts, its usefulness, if it became a law, would be quite seriously affected. It provides that the representatives of the regular school shall never form a majority of the Board, and it compels all the State Medical Colleges to adopt four-year courses. The former provision is an absurd and unjust concession to decaying and dishonest superstitions.

The latter provision is a little premature, and would only send a rush of students to the cheap two-year medical colleges of this city.

News of the Week.

DR. FORDYCE BARKER'S PARIS DIPLOMA.—The numerous friends of Dr. Barker will read with great pleasure the facts concerning the reception of his heretofore much-talked-of Paris diploma as related in Dr. Morrow's interesting letter in this issue. Dr. Barker's assertions were never doubted, but it is gratifying, even at this late date and in this strangely roundabout way to have them so directly and positively corroborated. We congratulate Dr. Barker accordingly.

THE INTERNATIONAL MEDICAL MISSIONARY SOCIETY held its eighth annual meeting in this city on April 21st. The Society educates medical missionaries, and, we are told, runs six dispensaries in this city.

THE INTERCOLONIAL MEDICAL CONGRESS, which recently had a successful meeting at Sydney, has adjourned to meet at that place in the year 1892.

INHALATIONS OF CHLOROFORM (Clemens), the artificial production of rheumatism by transfusing the blood of rheumatics (Lanigan), and the internal use of Homeriana (Laskoff) are among the latest specifics for the cure of phthisis pulmonalis.

THE PNEUMONIA COCCUS AS THE CAUSE OF ACUTE OTITIS MEDIA.—Professor E. Zaufal (*Prog. Med. Wochenschrift*) reports four cases of acute otitis media in which the diplococcus pneumoniæ was the only micro-organism found in the discharges.

THE GERMAN SURGICAL CONGRESS met in Berlin this past week.

DR. CRAIK has been appointed Dean of the Medical Faculty of McGill University.

THE MEDICO-CHIRURGICAL COLLEGE of Philadelphia graduated a class of thirty.

THE COLUMBUS MEDICAL COLLEGE graduated a class of twenty-one.

THE VARIED AND READY TALENTS, the wide linguistic knowledge, and the apt and verbifacient resources of the gentlemen on the staff of THE MEDICAL RECORD are facts well known to our readers, a just enumeration of which would put a severe strain upon eulogistic polyonomy. It may not be so well known that one talented prop of our medical journalism has mastered Chinese, written a popular grammar and phrase-book of that language, and can write a prescription or decorate a tea-chest with mysterious and polymorphic characters that apparently breathe the deep joy of an ancient and Celestial origin.

SUING A STEAMSHIP COMPANY FOR INEFFICIENT MEDICAL SERVICE.—Miss Alice M. Allan has sued the State Steamship Company for alleged injuries sustained through the administering of a poison to her by an ignorant surgeon. Her story is that she asked for quinine, and the surgeon gave her a dose of mercury, which poisoned her.

INTERNATIONAL MEDICAL CONGRESS AT PARIS.—In response to some further inquiries regarding the International Medical Congress to be held at Paris this summer, we would say that there are to be eleven International Congresses, under government patronage, bearing directly on medical and sanitary matters. They are as follows: 1. Mental Diseases. 2. Forensic Medicine. 3. Diseases of the Ear and Throat. 4. Skin Diseases and Syphilis. 5. Climatic Treatment of Disease. 6. Therapeutics. 7. Hygiene and Demography. 8. Veterinary Medicine. 9. Poor Relief. 10. Dental Surgery. 11. Homœopathy. Besides this there will be a Congress on Criminal Anthropology, on Temperance, on Improving the Condition of the Blind, and on Securing Weekly Rest.

AN INTERNATIONAL HYGIENIC CONGRESS.—This Congress, which met at Vienna last year, will assemble in London in the year 1891, and already arrangements are in progress for its reception. A Provisional Committee has been formed, and a circular has been issued to all the leading public medical bodies, asking them to nominate representatives on the General Committee, which is in course of formation. The circular is signed by Sir Spencer Wells, Sir C. Cameron, Drs. Frankland, Humphry, and Mapother, Sir Douglas Galton, and Dr. Corfield.

THE BADGES OF PARISIAN STUDENTS.—The students of the various Faculties in Paris recently resolved to wear a distinctive form of headgear. In order to mark themselves off still more conspicuously from the non-academical multitude they have now adopted a special badge. Medical students are to wear a black and red rosette, with the tasteful device of a death's-head in the centre; students of pharmacy are to have a green rosette, with a silver palm tree, round which a golden snake is twined; while the law students have fixed on a black badge with a pair of scales in gold.

"DRUNAINE," the new Australian local anæsthetic, has recently been examined by Dr. Dixon, who finds it to be nothing but a mixture of oxalate of calcium with some phosphate.

THE ST. LOUIS POLYCLINIC is the name of another contribution to medical journalism and erroneous orthoepy. It is edited for St. Louis Post-Graduate School of Medicine, by L. A. Turnbull, M.D.

A NEW BUILDING has been added to Bellevue Hospital through the liberality of Mrs. R. H. L. Townsend, and through the agency of the New York Protestant Episcopal City Missionary Society. The building is three stories high, and situated in the rear of the hospital. It is in the nature of a reading-room and a chapel, in which the donor seriously requests that only the Episcopalian services be conducted.

WOMEN AS PHARMACEUTISTS.—The College of Pharmacy, at the Annual Commencement last evening, graduated one hundred and five young men, and three young women. Women ought to make good pharmacists, but we doubt if they will. There is a deep impression that they lack the sense of responsibility.

A LIBERAL GIFT TO ROOSEVELT HOSPITAL.—By the will of the late Wm. J. Syms, Roosevelt Hospital will receive $350,000. Of that amount $250,000 is to be used in the erection of a surgical operating theatre, at the easterly end of the lot on which the hospital stands. The theatre is to be under the direction of Dr. Charles McBurney, and to be called the "William J. Syms Operating Theatre of Roosevelt Hospital." The remaining $100,000 is to be invested, and the income applied to the expenses of the operating theatre.

DR. WM. F. WILSON, of Denver, Col., died on April 19th from an overdose of morphine.

THE INFLUENCE OF JABORANDI ON THE COLOR OF THE HAIR.—Dr. D. W. Prentiss, of Washington, reports a second case in which he thinks the use of jaborandi caused white hair to take its natural dark color again (*Ther. Gazette*). The patient was an old lady suffering from Bright's disease.

PROFESSOR NOTHNAGEL has been granted the title of Hofrath (Court Counsellor).

AN EPIDEMIC OF CEREBRO-SPINAL FEVER is said to be prevalent in Southern Texas. The disease runs a rapid and most malignant course, with very marked purpuric eruption.

A BUILDING FOR PHYSICIANS' OFFICES is to be built at Minneapolis. The building is to be eight stories, and cost $200,000. It is stated, incorrectly, that New York has two such structures. On the contrary, New York has none, and probably never will.

A FEE FOR SUCCESSFUL LAPAROTOMY.—Dr. Bernays, of St. Louis, was paid $500 by that city for successful laparotomy on a policeman who was shot through the stomach, duodenum, and jejunum.

DR. JOSEPH CHARLES PYNCHON, of Springfield, Mass., died on April 10th, from heart disease, after a sickness of several months. Dr. Pynchon was seventy-four years of age. He was a direct descendant of the founder of Springfield, and a nearly life-long resident of that city. He graduated from Williams College in 1836.

MYOPIA JUDICIALIS.—Dr. R. T. M——, of this city, writes: When the judge at Sioux City instructed the jury to find for the defendants in the "Faith Cure" case (THE MEDICAL RECORD, April 20th, p. 440), because it was no crime, under the laws of Iowa, for a person to pray for an afflicted neighbor, he ought to have been presented at the same sitting with the question which broke up the Squid Beach Debating Society, namely: "Is digging clams fishing or farming?" In a faith cure case the question is not as to whether it is right or wrong to pray for a neighbor, but rather the question as to whether praying constitutes sound and responsible legal or medical advice and management.

THE AMERICAN CLIMATOLOGICAL SOCIETY.—The next meeting of The American Climatological Association, Dr. V. Z. Bowditch, President, will hold its annual meeting in Boston, June 24th and 25th, just prior to the meeting of the American Medical Association at Newport.

ALABAMA HAS A MEDICAL COLLEGE, located at Mobile. So writes a correspondent, correcting a statement of ours in a previous issue.

MALPRACTICE SUITS IN CALIFORNIA.—California physicians seem especially subject to unfortunate and unjust libel suits. The latest victim is Dr. C. N. Ellinwood, Professor of Physiology in Cooper Medical College, who is sued for $5,000 damages by a young woman on account, as she alleges, of being treated for epilepsy when she had apoplexy, and by the mental anguish she had endured from being pronounced pregnant when she was chaste. We learn from the *Pacific Medical Journal* that there is a bill before the California Legislature requiring all persons who sue for damages to "put up" $500, first.

THE PERIODICAL LIST OF THE LIBRARY OF THE NEW YORK ACADEMY OF MEDICINE.—The journal list recently prepared by Mr. John S. Brownne, librarian of the New York Academy of Medicine, shows the richness of the library in periodical and serial literature, and will prove an important help to those consulting it. Part First contains a list of all the periodicals, transactions, reports, and serials published in the United States and Great Britain. All those classes of publications placed under the above heads in the Index-catalogue of the Surgeon-General's library are also included here. Hence, serial publications like "Ziemssen's Cyclopædia," "Wood's Medical Library," etc., are included. Mr. Brownne's list is evidently prepared methodically and with much care. It is an improvement in some details over that of the Surgeon-General's catalogue, as for example in indicating by figures that the periodical is still current. We trust that the annotation of "wants" will be borne in mind by those who consult the catalogue.

THE USE OF ALCOHOL IN BOND BY SCIENTIFIC INSTITUTIONS.—It may not be generally known that the internal revenue tax on alcohol is remitted under certain restrictions to various institutions of learning. The section of the Revised Statutes of the United States authorizing this remission, reads as follows: "The Secretary of the Treasury may grant permits to any incorporated or chartered scientific institution or college of learning to withdraw alcohol in specified quantities from bond without payment of the internal revenue tax on the same, or on the spirits from which the alcohol has been distilled, for the sole purpose of preserving specimens of anatomy, physiology, or natural history belonging to such institution, or for use in its chemical laboratory. Also to any scientific university or college of learning created and constituted such by any State or Territory under its laws, though not incorporated or chartered." In reply to a letter of inquiry from the Superintendent of Roosevelt Hospital, the acting Secretary of the Treasury defines the uses to which free alcohol may be put, in addition to the preservation of specimens, as follows: "1. In the manufacture in your chemical laboratory of tinctures, liniments, and other pharmaceutical preparations for use in the hospital wards and in the out-patient department. 2. As a lotion for bathing the afflicted parts of the patients under treatment in the hospital and out-patient department. 3. As an antiseptic wash by the surgeons before and after operations in both departments. 4. As an antiseptic solution for cleansing surgical instruments. 5. As an antiseptic solution for preparing and preserving catgut ligatures, to be used in surgical operations. 6. For burning in spirit-lamps, principally in the analysis of urine." It is distinctly provided, however, that the alcohol and the preparations mentioned shall be used only in the manner described, and shall never be sold to any person inside or outside the hospital.

Reviews and Notices of Books.

JAHRESBERICHTE ÜBER DIE FORTSCHRITTE DER ANATOMIE UND PHYSIOLOGIE. Sechzehnter Band, Literatur, 1887. I. Abtheilung. Anatomie und Entwickelungsgeschichte. Leipzig: Verlag von F. C. W. Vogel. 1888.

THIS annual volume is a carefully edited review of the literature covering the special subjects of anatomy and embryology.

INTRACRANIAL TUMORS. By BYROM BRAMWELL, M.D., F.R.C.P.E., F.R.S.E. With one hundred and sixteen illustrations. Pp. 270. Philadelphia: J. B. Lippincott Co. 1888.

THE present interest in cerebral surgery makes Dr. Bramwell's work a timely one. He has undertaken to give a systematic account of the symptoms, diagnosis, morbid anatomy, etc., of cerebral tumors. He bases his account largely on his own personal experiences and includes many reports of cases not hitherto published. The work has, therefore, a special value, but lacks some of the importance that would be attached to it if it attempted to cover in a complete way the whole subject of cerebral tumors. The illustrations, for which kind of work Dr. Bramwell has gained a deserved reputation, are numerous and are executed with great skill. A final chapter, on "The Surgical Treatment of Intracranial Tumors," by Arthur W. Hare, is hardly so exact or complete as it should be.

ELEMENTS OF PRACTICAL MEDICINE. By ALFRED H. CARTER. Fifth edition. London: H. K. Lewis. 1888.

THIS text-book, which, during eight years, has reached its fifth edition, commends itself to the student of medicine by its terse and clear style, its avoidance of unnecessary details, and, what is difficult in a compendium, its proper arrangement of symptoms so as to impress them upon the mind in their relative importance.

A Manual of Diseases of the Nervous System. By W. R. Gowers, M.D., F.R.C.P. American edition. With three hundred and forty-one illustrations. Pp. 1,357. Philadelphia: P. Blakiston, Son & Co.

The American publishers have combined the two volumes of the English edition into one, making a somewhat formidable but perhaps more convenient book. The writings of Gowers are familiar to American readers through his smaller works on "Diagnosis," "Epilepsy," and "Ophthalmoscopy." The expectations raised by the excellence of his previous work will not be disappointed. Dr. Gowers has written one of the most complete and admirable text-books on nervous diseases. The book is copiously illustrated with cuts, showing pathological conditions and clinical cases. The descriptions of cerebral anatomy are fairly complete.

The portions especially instructive are those on epilepsy, on the anatomy and diseases of the cranial nerves, and most of the articles on diseases of the cord. The discussion of the muscular dystrophies is not so satisfactory, and it will be a disappointment to American readers to find practically nothing said about the neurasthenic states.

Therapeutics: its Principles and Practice. By H. C. Wood, M.D. Seventh Edition. Pp. 908. Philadelphia: J. B. Lippincott Co. 1888.

This valuable work of therapeutics is so well known and appreciated by the profession that it needs no words of commendation from the reviewer, whose task, therefore, is only to point out wherein the seventh edition differs from its predecessors. The author in his preface states "that comparatively few persons have a full conception of the rapid progress of therapeutics and the amount of labor involved in keeping up with this forward movement. Scarcely three years have elapsed since the appearance of the sixth edition, yet the preparation of the present volume has necessitated a careful study by its author of nearly six hundred memoirs." He also calls attention to the special growth in the medical profession of the appreciation of the value of remedial measures rather than drugs, and he discusses these in Part I. of his book, in which he considers massage, metallo-therapy, feeding of the sick; treatment of general bodily conditions—such as exhaustion, obesity, and the gouty diathesis; heat and cold, and electricity. One turns also with interest to the consideration of the many new drugs concerning which, in the last three years, so many conflicting or corroborating accounts have been written, to find what has really crystallized with reference to them and their application.

Notwithstanding the author's efforts at condensation, this edition contains nearly two hundred pages more than former editions.

Practical Anatomy: a Manual of Dissections. By Christopher Heath, F.R.C.S. Philadelphia: P. Blakiston, Son & Co. 1888.

This is the seventh edition of this well-known text-book. It has been carefully revised by Mr. Rickman Godlee, new wood cuts added, and the sections in the thorax and the brain have been enlarged. The plates are very clear and fine; their utility would, however, have been greatly enhanced if, instead of numbers referring to a list of the names of the different objects depicted, these names had been printed on the plate, so that the student at a glance could see what he is looking for. This method of labelling the parts used in "Gray's Anatomy" has, doubtless, been one of the chief reasons of its great and continued popularity.

A Text-book of Physiology. Part I. By M. Foster, M.A., M.D., LL.D., F.R.S. Fifth edition. London and New York: Macmillan & Co. 1888.

Part I. of Foster's "Physiology" relates to blood, the tissues of movement, and the vascular mechanism. It has the familiar look of the former editions. It has the same involved style, which would have killed an ordinary text-book. The author has seen the necessity of adding and increasing the histological information. It is in this direction that the main difference between this and preceding editions is found. It is to be regretted that illustrations have not been introduced, as a good plate serves to impress upon the mind a clearer idea than pages of descriptions of minute anatomical details.

Inebriety: its Cause; its Results; its Remedy. By Franklin D. Cann, M.D. Philadelphia: J. B. Lippincott Co. 1888.

In treating of the causes and results of inebriety the author writes in the serious and popular style of the ordinary temperance lecturer, who talks of "jingling glasses" and "glittering saloons." The professional reader will turn first to that portion of the book which deals with treatment and management of inebriety, but he will not be startled by any new ideas; he will rather find it useful in reminding him of what he has seen or read before.

Physician's Interpreter. In Four Languages. Specially arranged for Diagnosis. By M. von V. Philadelphia: F. A. Davis. 1888.

This is a collection of sentences designed to facilitate intercourse between a physician and his patient when neither understands the language of the other. The sentences are well chosen, and the book will be useful to one who is studying either German, French, or Italian, and who desires to familiarize himself with the medical terms in these languages. But one who is wholly ignorant of the language of his patient will have difficulty in making himself understood without some knowledge of the pronunciation, and, even if he does succeed in this, will be unable to gather much information from the answers of the patient. Many blank pages are inserted upon which the student may jot down any new sentences that he may be able to pick up from any source. The book is of a convenient size to be carried in the pocket.

Alpine Winter in its Medical Aspects. By A. Tucker Wise, M.D., L.R.C.P., etc. Fourth Edition. London: J. & A. Churchill. 1888.

The treatment of chest diseases in the mountains has become one of the recognized resources of therapeutics. The practice itself is founded upon a solid basis of fact, but the detailed information necessary to the proper selection of localities in the mountains adapted to the varying exigencies of chest-troubles has not always been forth coming. This want has been met in the present publication, which gives the important facts bearing on Davos, Platz, Wiesen, St. Moritz, and the Maloza, as health resorts.

Beiträge zur pathologischen Anatomie und Physiologie. Herausgegeben von Dr. Ernst Ziegler und Dr. C. Nauwerck. Zweiter Band, Drittes Heft; Dritter Band, Erstes Heft. Jena: Verlag von Gustav Fischer. 1888.

We take pleasure in calling attention to this series of original contributions to pathology, which in the volumes before us are both numerous and valuable.

Text book of Medical Jurisprudence and Toxicology. By John J. Reese, M.D., Professor of Medical Jurisprudence and Toxicology in the University of Pennsylvania, etc. Second edition. 12mo, pp. 638. Philadelphia: P. Blakiston, Son & Co. 1889.

The second edition of this standard work has been revised and comes to us with some important additions, in the subjects of Suffocation, Malpractice, Blood Stains, Ptomaïnes, and General Toxicology. It may now be looked upon as a complete manual of its kind, and well calculated for profitable reference by the general practitioner.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON THEORY AND PRACTICE OF MEDICINE.

Stated Meeting, February 19, 1889.

R. C. M. PAGE, M.D., CHAIRMAN.

DR. A. L. STERN exhibited

WEIGERT'S HOT-AIR INHALATION APPARATUS, FOR THE TREATMENT OF PULMONARY TUBERCULOSIS.

This consists of two cylinders of copper, one within the other, and the air to be inhaled, which is heated to a minimum temperature of 212° F. by means of a Bunsen burner, and thus rendered perfectly aseptic, passes up between the two. The inhalation is to be used for four hours each day, two hours at a time, and it can be taken either in a sitting or reclining posture. It is advised, however, that when first commencing the treatment the patient should use the apparatus for only thirty minutes, twice a day. The temperature of the air inhaled is gradually increased from 212° F. to as high a point as the patient can bear without suffering inconvenience, 482° F. being the highest temperature as yet reached in any case in these inhalations. Dr. Weigert, the inventor of the apparatus, is a graduate of the College of Physicians and Surgeons of New York, but is now residing in Berlin.

As a result of the hot-air inhalation, Dr. Stern said, there is an acceleration of the pulse, while there is a diminution in the frequency of the inspirations, and the inspirations become deeper. There is at first an elevation of the temperature, the rise being from one to two degrees; but after about an hour the temperature again subsides. The difficulty of breathing incident to consumption is soon markedly relieved, and there is at first a lessening and then a total cessation of cough. Under the use of the inhalations there is at first an increase, then a decrease, and, finally, total disappearance of expectoration. All catarrhal symptoms disappear, and also the fever and night-sweats. There is a clearing up of the infiltrated portions of the lungs, and cicatrization of cavities, where these exist, is brought about; while the strength, weight, and appetite of the patient gradually increase. The microscopic examination of the sputa generally shows at first an increase in the number of tubercle bacilli, but afterward there is a total disappearance of the bacilli, and a complete cure of the case is effected. The shortest period in which total disappearance of the bacilli has been noted is four months. This method of treatment, he said, in conclusion, has now been employed in one hundred and fifty cases, fifty of which are published in Vienna, and the Chairman stated that it has been successfully practised in this country by Dr. Trudeau, of Saranac Lake, N. Y.

DR. S. SEABURY JONES read a paper on

SIMPLE, NON-TUBERCULAR, NON-METASTATIC ABSCESS OF THE LUNGS.

This was a subject, he said, which had received but little attention. Simple abscess of the lungs was, however, comparatively rare, and it would doubtless occur more often than it does were it not, as Stokes had pointed out, that the lungs are provided with such an admirable natural system of drainage through the bronchial tubes. Practically speaking, it was liable to be met with in one of four forms. The first was that in which the symptoms were very obscure from the beginning and remained so until there suddenly occurred a discharge of purulent matter. In the second form the symptoms resembled those of pleurisy with effusion, and in the third those of pulmonary tuberculosis. The fourth form was that associated with the variety of pneumonia which advances slowly from one lobule to another, or is characterized by a tendency to skip from one lung to the other.

Dr. Jones said that he had personally met with all the forms except the first, but undoubted cases of this kind, occurring in the experience of others, were on record. Abscess of the lungs, he went on to say, was always accompanied with a depreciation of the general health, and alcoholism was apparently a prominent factor in its production. It was an affection confined to no particular age, and in 1887 Dr. L. Emmet Holt, of this city, had reported in THE MEDICAL RECORD a case that occurred in an infant only three months old. When he encountered his first case, now nine years ago, he was unable to find any reference to the subject, whatever, in any of the text-books. This case he then proceeded to narrate. The patient was a young man, seventeen years of age, of rather delicate general health and affected with slight lateral curvature of the spine, and he first came under observation, September 25, 1879. He was in his usual health, when he was attacked with severe pain in the left side, accompanied with cough, but no expectoration. At the time he was seen the pulse was 120 and the temperature 102° F. Anteriorly there were no abnormal physical signs, but posteriorly, in the subclavicular region on the left side, there was complete dulness on percussion, although no râles whatever could be found. There was still no expectoration. About October 1st a large abscess of the tonsil developed, from which pus discharged freely; and subsequently there was a discharge of purulent matter from the lungs through the mouth. After this the patient made a rapid recovery, and had no further trouble afterward.

He was led to consider this as a case of simple abscess of the lungs, first, on account of the short time intervening between the first symptoms and the discharge of pus; secondly, on account of the occurrence of the tonsillar abscess showing a tendency to the formation of abscesses in the system; thirdly, from the rapidity of the recovery; and, fourthly, because of the dulness found on physical exploration being exclusively posterior. He was afterward confirmed in his opinion in regard to the nature of the case by the report of a case published by Dr. Henry Payne in *The Lancet*, in 1882.

The patient was a male, twenty-three years of age, who was admitted to the Ashton-under-Lyne Infirmary in June, 1881, with well-marked signs of pleuritic effusion on the left side; the trouble having commenced in the previous February with chills, pain in the side, and feverishness, the result of getting wet through. He was treated for pleurisy at this time, and recovered sufficiently to attend to his work until April, when he experienced difficulty in breathing, shortness of breath, and slight cough. He spat blood once or twice, and continued to grow worse until his admission to the hospital in June. He was treated, without improvement, until August 20th, when the following condition was noted: The patient has lost flesh since admission. The left side bulges more than the right and measures an inch more round; movements on this side are deficient; there is absolute dulness on percussion, both back and front; no breath-sounds are heard, and the vocal fremitus and resonance are absent. The breathing on the right side is exaggerated. He has a slight cough, but no expectoration of any importance. Has night-sweats; the temperature every evening has been above 100° F., and the pulse invariably above 100.

From these symptoms an empyema was suspected, and an exploratory puncture discovered pus. Accordingly, upon August 23d, an incision about two inches long was made just above and parallel to the seventh rib in the anterior axillary line, antiseptically and under chloroform. Upon opening the pleura there was very profuse hemorrhage of dark venous blood, which could only be arrested by the injection of bichloride of iron solution. About fifteen ounces of pus escaped, and a drainage-tube was inserted. There was a very profuse discharge, which in a few days became fetid. He continued to do fairly well until the 29th, when the temperature suddenly rose to

104° F.; and, after suffering some pain in the chest, he died on the 30th. The autopsy showed the whole of both surfaces of the left pleura adherent, without a drop of fluid in the sac. The external opening made in the chest-wall led into a large irregular cavity, situated in the centre of the lung, which was in a state of gray hepatization. Dr. Payne regarded it as undoubtedly a case of pneumonia, ending in the formation of an abscess.

Dr. Jones' second case was observed in 1886. The patient was a male, forty years of age, who was attacked with tonsillitis. There was suppuration, accompanied with pus, which was ushered in by a chill, and on an incision being made in the tonsil there was a considerable discharge of pus. Subsequently he had another severe rigor, followed by high temperature, and coughed up a cupful of pus and dark blood. Still later there was another attack of a similar character. In this case there was an area of dulness at the base of the right lung, with local tenderness on pressure. The matter coughed up was found, on microscopical examination, to contain the pneumococcus of Friedländer.

This third case was one in which the symptoms resembled those of tuberculosis. The patient was first troubled with palpitation of the heart, which he believed to be due to gastric derangement. There was a considerable loss of flesh (amounting to forty pounds), and the temperature ranged from 100° to 102° F. Physical examination revealed an area of dulness in the right subclavicular region. Dr. Jones prescribed quinine and a general tonic treatment, and sent him to the country for the summer. In July he coughed up a considerable quantity of pus and dark-colored blood. Afterward the expectoration was profuse, and he suffered from night-sweats and became greatly emaciated. He then began to improve, and, as repeated examinations of the sputa failed to detect at any time the presence of the bacillus tuberculosis, the case was regarded as one of simple abscess of the lungs, and a favorable prognosis made. In a few weeks the patient regained his usual health and weight, although a small cavity still remained in the lung. Two years afterward he was seen in excellent health, and no sign of a cavity could be detected.

He next narrated a case reported in *The Lancet* in 1884 by Mr. T. Pridgin Teale. The patient was a male, fifty-four years of age; had been ill for three months, and the earlier history of the case was very obscure, commencing with a cold shivering, loss of flesh, vomiting and retching, and pain in the hepatic region, but without cough or any symptom of lung disease. About two weeks before he was seen by Mr. Teale, Dr. Clifford Albutt found the hepatic dulness increasing upward, as if there were fluid in the lower part of the thorax, and a week later Dr. Myrtle saw the patient, and, finding dulness occupying the lower half of the right lung, came to the conclusion that fluid was present and advised early tapping. The right side of the thorax was accordingly punctured low down with the small trocar of Bartlett's aspirator; but only two drachms of fluid—clear and straw-colored—could be obtained with the suction of the aspirator. Being still confident that fluid was present, Mr. Teale made a fresh puncture higher up, when very offensive, thin, greenish pus appeared, and after careful and continuous aspiration about a pint of pus was slowly withdrawn. In consequence of the unexpected character of the case, two days later a consultation was held, and it was decided that, as soon as the temporary relief afforded by the tapping had passed by, the thorax should be opened and drained. By a fortnight afterward the patient had become more hectic, had expectorated for two days most offensive pus, and was altogether extremely ill. On the right side there was continuous dulness, extending upward in front to about the level of the fifth rib, a little below the nipple, and laterally around the axilla, and diminishing toward the spine. In the recumbent posture there was a spot in the front of the chest having a peculiar "cracked-pot" resonance in the middle of a dull area. No râles. An incision was made at the cite of the puncture and the pleural cavity opened. No pus appeared; only a small quantity of serum. The lung felt dense and boggy; not crepitant and elastic. On reintroducing the trocar and puncturing the lung, pus appeared. The puncture was enlarged so as to admit the finger, and two pints of exceedingly fetid pus escaped. A drainage-tube was inserted, and the cavity syringed out with a weak solution of carbolic acid. The after-progress of the case was extremely tedious and critical, but the patient finally made a good recovery.

Trousseau stated that for his first twenty five years of hospital practice he had never met with a case of simple abscess. Afterward he found two cases. Laennec met with only five cases in several hundred autopsies in those who had died of pneumonia. "Moreover," he wrote, "they were inconsiderable, few in number, and scattered through the lungs, which presented the third degree of inflammation." In 1848, Robert Graves reported six cases.

Simple abscess of the lung was no doubt more frequent, however, than was generally supposed, and in the future it would be more easy to recognize than formerly, since Koch's brilliant discovery of the bacillus tuberculosis now enabled us to make a differential diagnosis. In Pepper's "System of Medicine" some attention was given to the affection, and it was defined as a circumscribed suppuration of the lung, resulting in a cavity. In Von Ziemssen it was referred to only as a sequel of croupous pneumonia. In 1885 Dr. Andrew Dunlop described an interesting case in *The Lancet* in a man, fifty-three years of age, of intemperate habits. Dulness on percussion, with weak breathing, was observed below the right nipple. This gradually extended upward until, in about a week, there was dulness, with almost inaudible respiration, up to the second rib. Posteriorly there was dulness about two inches upward from the base, with weak, rough respiration. Shortly afterward a prominence of considerable extent was noticed in the mammary region. This tumor seemed to originate beneath the ribs, which were bulged outward by it, and it was hard to the touch. The tumor was aspirated, and about ten ounces of pus withdrawn, which was followed by some subsidence of the tumor. At the end of a month the upper part of the tumor was less prominent, while at least the upper half of it was tympanitic on percussion. During this time the patient had been spitting up an ounce or two of curdy pus daily, and during the last ten days it had also been escaping from the puncture made by the aspirator-needle to the extent of one or two ounces in the twenty-four hours. He gradually failed, and died about two months and a half later.

Lassen, of Kiel, had reported 6 cases. Runeberg, of Sweden, had collected 8, including 1 of his own, and including the 3 cases narrated in the present paper. There were now on record 30 well-authenticated cases, exclusive of Graves' 6 cases, all of which recovered. Of the 30, 16 were operated on, and 14 were not operated on. Of the former, 4 died, and of the latter, 2. The main point, where an abscess had manifested itself, was to decide between tubercular and simple abscess. The rapidity of the development of the symptoms was always in favor of simple abscess, but the real test was to be found in the microscope. If, in any case, an operation was decided upon, free incision was no doubt the best procedure. Dr. Jones said he had not been favorably impressed with the results attained from the injection of tuberculous cavities. He would only operate, however, when an operation was clearly indicated.

DISCUSSION.

The Chairman, DR. PAGE, said the paper was quite a revelation to him. He had personally never met with a case of pneumonia terminating in abscess, and Wilson Fox and other authorities had stated that abscess of the lungs was very rare. Nothing had been said in the paper in regard to pulmonary abscess resulting from the presence of foreign bodies. He had seen a case in which an abscess

developed on account of the presence of a bullet which had entered the lung-tissue twenty years before, the patient having been wounded in one of the battles during the late war. He was thought to have a cavity, and was troubled with cough and hemorrhage. The case resulted fatally, and at the autopsy an abscess with the bullet in it was found. Reynolds related a similar case in an old Waterloo soldier, where the bullet remained in the lung for forty years before the abscess developed.

Dr. Alfred L. Loomis said that the paper, with its three original cases and its records of other cases, constituted a valuable contribution to the somewhat meagre literature of this subject. In his own experience, simple abscess of the lung was very rare. He had, however, seen a very few cases which were regarded, and very properly, he thought, of this nature, and in one or two instances the diagnosis was proved by post-mortem examination. In all cases, so far as his knowledge went, where abscess had been observed, it had been preceded by the signs of inflammation, more or less active, and it occurred in those in a condition favoring the development of abscess. He believed that such abscesses formed in lungs which were previously the seat of fibrinous pneumonia followed by an increase of connective tissue. When subjected to a chronic inflammation, not very active, abscesses were liable to form in this tissue. Such abscesses also occurred altogether in alcoholic subjects, and he had never seen them in any other. There was one point which Dr. Jones had touched upon that he wished to call attention to. It was, in his opinion, very difficult to draw the line between circumscribed empyema in certain positions and abscess of the lung, and especially if such empyema broke into the bronchial tubes so as to allow of the escape of pus. He thought that he may have made such a mistake himself. In any case of his own he should be very loath to pass a knife into the lung-tissue, and he fancied that the necessity for such a procedure was very rare. As a rule, it diminished the chances of the patient's recovery, and it was better to leave the abscess to open spontaneously. We were certainly indebted to Dr. Jones for directing attention to this subject, and urging greater care in the matter of diagnosis.

In closing the discussion Dr. Jones said that in two of his cases he had the opportunity to examine the sputa, and as there was in both instances an entire absence of the tubercle bacillus, it was on this that he based his opinion of this non-tuberculous character.

Dr. Frederick Peterson read a paper on

ANODAL DIFFUSION.

He said a more exact title for his paper would be "Electric Cataphoresis as a Therapeutic Measure." He spoke first of the remarkable series of experiments in voltaic narcotism for the production of local anæsthesia by Dr. Benjamin W. Richardson, as recorded in several papers published in the *Medical Times and Gazette* in the year 1859. The fluid which he used was composed of equal parts of tincture of aconite and chloroform. He had unfortunately abandoned the investigation of the matter soon after this, and it slumbered for more than twenty-five years. In 1886 Wagner published the excellent results which he had obtained in producing local anæsthesia by moistening the anode with a solution of cocaine, and the matter was then taken up by a number of observers. Among these was Dr. J. Leonard Corning, of this city, who published an article on the subject in the *New York Medical Journal* in November, 1886. For introducing the cocaine he employed an instrument resembling that of Baumscheitt, but provided with many more fine needles. Dr. Corning, however, did not publish any results in cases. Dr. Peterson exhibited the instrument devised by Adamkiwicz, which he criticised as unphilosophical in construction, and later presented an apparatus which he had devised himself, and which he said had proved very satisfactory in his hands. He had made over one hundred careful experiments, and about one-quarter of these he briefly related. The medicinal agents which he had principally employed were cocaine and aconitia, and he had found the method very successful in a number of neuralgic and other painful affections. There could be no doubt, he thought, that cataphoresis was produced by this means.

DISCUSSION.

Dr. Landon Carter Gray said that there was not much to be said, after Dr. Peterson's exhaustive paper. It was a new subject. He had got one of Adamkiwicz's instruments soon after they came out, and had obtained some results with it, but they were unfortunate results. He found its application quite painful, and in one case, where the patient was just recovering from an attack of acute articular rheumatism, he feared that he had induced a second attack by the use of the instrument. Because of the painfulness of the carbon-disk he had given it up, and since then, whenever he had occasion to resort to this method, he employed an ordinary sponge-electrode.

Dr. M. Allen Starr said the paper deserved the consideration of the profession, from the care used in the experiments recorded in it. Personally he considered this a very valuable method in the treatment of pain. In one of the cases cited by Dr. Peterson, where the patient was affected with locomotor ataxia, he had been a witness of the relief afforded. There was, however, one objection which he thought might be urged against this means of treatment, and that was the uncertainty in the matter of dosage. It seemed to him that it would be possible, however, by a series of experiments, to arrive at some definite knowledge in regard to this point. On one occasion he desired to use aconitia by this method, but he hesitated because he feared that a dangerous amount of the drug might be introduced into the system.

There was one other point which had not been brought out in the paper, and that was the applicability of this method to diagnosis as well as to treatment. By the use of cocaine, for instance, it was possible, in a case of *tic convulsif*, to determine which branch of the trigeminal nerve was affected. The injection of cocaine was disagreeable, and might cause abscess, and this method was therefore preferable to the use of the hypodermic syringe. He thought the method might also be employed sometimes to determine whether the pain in a given case was of peripheral or hysterical origin. If it were peripheral it would be relieved by it.

Dr. B. Sachs said that he had imported an Adamkiwicz instrument, but after trying it for a time he had not felt much encouraged to continue its use. In cases not very severe ordinary electric treatment gave as much relief, and, as a rule, he found that other means are quite as efficient as this, such as the hypodermic injection of morphia, cocaine, or aconitia.

While he was impressed with the cases of Dr. Peterson, he thought the latter should have appended other tests on the same patients. Thus the same troubles that were treated by the method described should have been treated by the anode alone, and by the drug alone, pressed upon the skin for the same length of time. The method at best was only palliative, and not curative. He did not agree with Dr. Starr that it afforded a means of differential diagnosis between peripheral neuritis and hysterical pain, because hysterical pain was apt to give way at any moment.

Dr. W. R. Birdsall said that he had had no practical experience with the method, but from the literature of the subject he had formed the opinion that it was of but little value. It seemed doubtful to him whether a sufficient amount of the medicinal agent employed could be introduced into the skin to cause the results claimed, and he was inclined to attribute whatever benefit was received in the cases in which it was tried to the anode alone. The depth to which such substances could be introduced was said to be very slight; but in many cases all that was needed was simply to bring the remedy in contact with the absorbents of the skin. He was glad to learn, how-

ever, that Dr. Peterson had found the method of greater value than he had supposed it to be, though he thought many experiments were necessary to decide positively as to its utility. When the nerves affected were superficial he would suppose it to be of the greatest benefit. When asked if he had found it of service in sciatica, Dr. Peterson had replied that he had not, because the nerves were too deep.

Dr. C. L. Dana said that he had obtained no satisfactory results with the Adamkiwicz instrument. Some time since Dr. Squibb had reported some very interesting experiments in which decided results were produced by the local application of various substances in connection with oleic acid, and with a preparation of it containing one per cent. of aconitia he had caused constitutional effects. No constitutional effects, however, had thus far been produced by the method in question, and he could not but agree with Dr. Birdsall that it was very superficial in its action. With the use of Dr. Peterson's formula he had produced anæsthesia in only one out of three cases, though this might have been perhaps due to some defect in the technique employed.

Dr. J. Arthur Booth said that Dr. Peterson's method certainly produced marked anæsthesia both to feeling and touch. As mentioned in the paper, one of the experiments recorded was made on his person, and the anæsthesia lasted for at least fifteen minutes. For some time afterward the part experimented on remained very sore and hyperæmic. He had tried it himself in three cases, and in one it afforded decided relief.

In closing the discussion, Dr. Peterson said that he agreed with Dr. Starr that the uncertainty of the dosage was one of the great objections to the method, but it was probable that by a course of experimentation such as the latter had suggested this difficulty would in time be obviated. As to Dr. Sachs' criticism that no parallel tests had been reported in the paper, he would say that in some of the cases the anode was used alone, and that no effects were observed except just at the time of its application. As to Dr. Birdsall's remark that the method was superficial in its action, and that the use of strong currents was required against strong resistance, in one or two of his experiments an imperceptible current employed for a longer time produced the same effects. There was, as had been said, an absence of constitutional effects, and as many of the experiments had been made upon his own person he could speak with some degree of assurance on this point.

DIFFUSE PIGMENTATION PRODUCED BY THE INTERNAL USE OF ARSENIC.

Dr. W. M. Leszynsky exhibited a little girl, nine or ten years of age, in whom the use of Fowler's solution, given for the relief of chorea, had produced very marked pigmentation all over the surface of the body. There was no reason whatever to suspect the presence of Addison's disease, he said, and the case seemed to him a most remarkable one. As to the prognosis as regards the permanency of the pigmentation, he was unable to express any opinion.

An Unusual Accident Attending Tooth Extraction.—To the record of the numerous casualties which may follow tooth extraction Mr. Ackery, at the Odontological Society of Great Britain, has added another probably unique case. A molar was extracted from a patient while under the influence of nitrous oxide gas; the apex of one root, however, was left behind. A sinus subsequently appeared, and this did not heal upon the removal of the remaining portion of the tooth. Eight years after the original operation a substance was discharged from the sinus, which proved upon examination to be the point of one of the jaws of a tooth-forceps, which had doubtless been broken and left in the alveolar process at the time of the endeavor to extract the tooth.—*The Lancet*, February 9, 1889.

Correspondence.

OUR PARIS LETTER.

(From our Own Correspondent.)

THE NATURE OF TETANUS—TREATMENT OF CYSTIC TUMORS—ZOÖPLASTIC GRAFTINGS WITH THE SKIN OF THE FROG—MEDICINE IN ORIENTAL COUNTRIES—SYPHILIS AS AN INCURABLE DISEASE.

Paris, April 5, 1889.

The prolonged reading of the subject introduced by Professor Verneuil at the Academy of Medicine, on the nature of tetanus, has been brought to a close. Besides the equine and telluric origin of tetanus, M. Verneuil believes also in the contagiousness of this malady, which may be effected by the dust floating in the air, or even by flies, as in the case of charbon. He cited a case in support of this last conjecture, without pretending, however, to arrive at a positive conclusion. In fact, M. Verneuil gives the preference to the equine origin of tetanus. In support of his thesis, he cites a statistic of about 380 cases. Of this number, 222 relate to individuals whose profession put them in constant relation with the horse (farmers, coachmen, stablemen, etc.), or fifty-eight per cent. As for the other cases, the equine origin of the malady, which may not appear so evident, is none the less real. For instance, three medical men, who died from tetanus, had horses which they looked after themselves, and a beadle, whose profession has nothing in common with that of the stableman, contracted the disease after having during a whole day, with a wound in the hand, transported manure from one place to another. As regards the telluric origin of tetanus, M. Verneuil sees in the earth only an intermediate agent between the horse and man. The soil impregnated with the dejections of the horse would be noxious; ordinary soil would not be so. Thus it was that, in the extensive works executed at the port of Boulogne, and where not a single horse was employed, not one case of tetanus was observed, although the wounds incurred by the workmen were numerous. Professor Verneuil concluded his communication by insisting on the means that should be taken to prevent the development of this malady. As it is now admitted to be contagious and microbian, all the articles that have been in contact with tetanic patients should be completely disinfected. A person wounded should never sleep in the bed previously occupied by a tetanic patient, without disinfection having been absolutely carried out. The equine origin of the malady being also established, the prophylactic measures should not be confined to man, but they should be applied also to horses. He recommends that the most energetic means should be employed, and he proposes not only the disinfection, but also the destruction of objects which, like the harness for instance, that had been used on tetanic horses, might contain the microbe of tetanus.

Dr. Barth, physician to the Broussais Hospital, has published a note on a new method of treatment applicable to synovial cysts, sebaceous wens and, in general, to all cystic tumors of the skin and of superficial regions. The beneficial results he had obtained by the interstitial injections of arsenic in the treatment of malignant lymphoma have induced him to try the same treatment in the above cases. Starting on the principle that arsenical injections determine a moderate inflammation of the tissues, which does not go on to suppuration when certain very simple precautions are taken, and which is often followed by an atrophic process, the author considered this remedy a convenient means of treating certain tumors which are benign in their nature, but are inconvenient, for which one often hesitates to advise a surgical operation. The first case in which Dr. Barth had occasion to try the procedure was that of a young girl twelve years of age, who was affected with a cynovial cyst of the wrist of several

months duration. This cyst, about the size of a small walnut, produced a very visible deformity. Moreover, it was extremely inconvenient for certain movements, the playing on the piano for example. Painting the part over with the tincture of iodine, frictions with divers resolvent ointments, prolonged compression, had been employed, but without any success. The author himself commenced by trying crushing of the tumor, but without effect, owing to the hardness of its parietes. He then resorted to an injection of two drops of pure Fowler's solution into the cavity of the cyst. The operation produced a sharp pain, and was followed the next day by swelling with tension of the sac; but this soon commenced to diminish in size, and ten days after the tumor had entirely disappeared without leaving the slightest trace of its existence. The author had occasion to employ this treatment in other cases of cystic or benign tumors, and with equal success.

Till now grafting on wounds has been practised with human skin, or with that of the common fowl. Dr. Dubousquet-Laborderie has tried zoöplastic graftings with the skin of the frog, and has obtained excellent results. For the success of the grafting he recommends the following rules: 1. The wound should be granulating, but the granulations should not be exuberant. 2. The operator must avoid causing bleeding and suppuration. 3. The patient should remain immobile for the first two or three days. 4. The dressings, which should be rigorously antiseptic, should be applied by the medical attendant himself. The first dressing should be compressive.

At a recent meeting of the Academy of Medicine, Dr. Le Roy de Méricourt read a report on the "Influence of Western Medicine in the Extreme East." Protestants, he said, have perfectly understood the importance which medical men acquire in oriental countries. They have established in China veritable medical missions, where medicine is taught to the Chinese, who will soon become practitioners and confirm the renown of Anglo-German science. He observes with some regret that nothing analogous has been done by the Latin peoples. M. Radiguet, former consular agent in China, had drawn the attention of the Academy to this sad state of things. Dr. Le Roy de Méricourt associates with this gentleman to ask the Academy to encourage the foundation in China of French missions, where medicine and surgery will be practised and taught.

Apropos of the correspondence being published in the English medical press, on the declaration recently made by Dr. Gowers to the effect that syphilis is incurable, I may here cite the following note, published in the *Gazette Hebdomadaire*, on the re-infection of syphilis, which may have some bearing on the subject: "Ricord says that an individual once in possession of syphilis is never free from it. Barensprung is of an analogous opinion, but he adds that, in syphilis, things take place as in the acute exanthematous affections, that the patient acquires a relative immunity in this respect. Sigmund absolutely denies re-infection; Zeissl, on the contrary, pretends to have observed it several times, some years after a first attack. Dr. Neumann cited several striking examples of re-infection."

The editor of a medical journal writing on the properties of saccharin, facetiously remarks that superior councils differ in opinion, according to the latitudes that they are in, on the merits of this valuable substance. The Council of Health of the Austro-Hungarian Empire, has declared that the employment of saccharin in the manufacture of alimentary products is not injurious, that saccharin is not toxic, and that it is even a precious substance, provided it is well prepared.

Food Adulteration in Paris.—The director of the laboratory of the police department in Paris has been detected accepting bribes from tradesmen accused of adulterating their goods, even having established a system of blackmail based on threats of exposing adulteration.

LETTER FROM THE SANDWICH ISLANDS—CAUSES OF THE DEPOPULATION OF THESE ISLANDS—THE DEMOGRAPHIC EFFECTS OF INTRODUCED DISEASES—SYPHILIS, LEPROSY—DR. BARKER'S DIPLOMA.

To the Editor of The Medical Record.

Sir: I send you a few hastily written notes of my observation of matters medical in the Sandwich Islands, which I trust may prove of interest to your readers.

From a sociological as well as from a strictly medical stand-point the Sandwich Islands present many features of interest to the observer. Situated in the midst of the ocean, continually swept by balmy breezes, with a tropical luxuriance of vegetation, these islands have been termed the "Paradise of the Pacific." They are inhabited by a race *facile princeps* among the Polynesian races in points of physical development, intelligence, and modes of living, with a delightful climate, a productive soil, sustaining no hardships, and yet dying at a most rapid rate. At the time of Captain Cook's visit, a little over a century ago, the population was estimated at not less than four hundred thousand, but the contact of civilization has acted like a blight upon the Hawaiian people; under its withering influence the native population has dwindled down by tens of thousands each decade until to-day it does not exceed thirty-five thousand.

It would be interesting to trace the causes which have led to the depopulation of these islands. No unfavorable influence of soil, climate, or hardship can be invoked in explanation of the decay and death of the native race. It is not the outcome of a contest between a savage and a civilized race in which the weaker succumbs to the stronger, as in the case of the North American Indian. Nor does it seem to be an example of the "survival of the fittest," since there is no competitive struggle for subsistence in a land where nature is so kindly and bountiful and furnishes an abundance of easily procured food, more than sufficient for the needs of all. Under the same conditions which have led to the depletion of the Hawaiian race and which seem to threaten its ultimate extinction, the foreign races that have settled here have taken root and flourished, and now virtually "occupy the land."

In endeavoring to appreciate the influences which have operated as factors in this extraordinary depletion of the population, the physiological peculiarities of the native should perhaps be considered among the contributing causes. The Hawaiian presents a curious combination of strength and weakness, or, rather, of seeming vigor masking actual effeminacy. He has a fine frame, well nourished—the embodiment, to all appearances, of bodily vigor—and yet his physical fibre is essentially weak and he is endowed with but a feeble vital tenacity. He succumbs to the shock of hardships or trivial ailments which would not seriously affect a white man. When he becomes sick he is not buoyed up with a desire and determination to live—he simply surrenders to fate and lies down to die. He takes life gayly and luxuriates in its enjoyment. He accepts death with the same cheerful alacrity. In fact, he dies often from no apparent cause other than an apathetic indifference to life.

Many curious cases might be cited illustrating the extraordinary influence of the mind over the body and proving that psychology may be a powerful agency of death as well as a means of cure. The kahuna or "medicine man" is invested by traditional superstition with supernatural powers which entirely overshadow those attributed to his civilized congener "the faith-cure man." He holds in his hands the issues not only of life but of death, and does things undreamed of in the "Christian science" philosophy. When a native is ill he is persuaded that his sickness is due to the agency of some demon or that he is being "prayed to death" by a kahuna employed by his enemy. Unless he can secure the interposition of a more powerful kahuna to break the spell he gives up hope and the ghost soon afterward, and

dies, often with no evidences of physical disease which the most expert diagnostician can discover.

The demographic effects of introduced diseases in a virgin soil can nowhere better be studied, and they exhibit facts of the most remarkable interest. The natives have proven strangely susceptible to the diseases of civilized life, and trifling ailments such as measles, whooping-cough, etc., acquire by their transplantation into this soil all the virulence of a fatal pestilence. Measles and whooping-cough, introduced in 1849, almost decimated the population—the mortality was excessive, almost every case terminating fatally. The ravages of small-pox, introduced in 1853, were none the less frightful. In the island of Oahu over fifteen thousand died, and the Marshal of the islands informed me that he superintended the burial of ten thousand victims of this disease in Honolulu alone—more than one-half of its entire population. The rapid spread and the excessive mortality of these diseases were attributed to the intimate social relations of the natives, their disregard of precautions, and their free use of cold water upon the first accession of febrile symptoms. It is one of the characteristics of the Hawaiian that the most disgusting disease excites no sentiment of repulsion or suggests the separation or isolation of the sick.

The most important agency in the depopulation of the islands has been attributed to syphilis, which was introduced by Captain Cook and his men in 1778. The licentious habits and promiscuous intercourse of the inhabitants caused it to spread like wildfire through the islands. In explanation of this rapid and universal diffusion of a disease strictly venereal, the "free and easy" and ultra-communistic customs of the social life of that period may be cited. A round of visiting was the chief diversion of the native, and the laws of Hawaiian hospitality required that the host should not only furnish his guest with food and lodging, but provide for his entertainment the women of his family. This was the universal custom, the neglect of which was regarded as a most unpardonable breach of etiquette. It is said that one of the severest trials of the early missionaries in their tours through the islands, scattering the seeds of Christianity, was the constant obtrusion of this St. Anthony form of temptation.

In a recent paper read before the "Honolulu Social Science Association," November, 1888, the Rev. S. E. Bishop thus comments upon this point: "It may be said in general that chastity had absolutely no recognition. It was simply a thing unknown and unthought of as a virtue in the old domestic life of Hawaii. A woman who withheld herself was counted sour and ungracious. This did not exclude more or less of marital proprietorship involving an invasion of the husband's right in enjoying his property without his consent. There was no impurity in it, any more than among brute animals. There was, however, a salutary limitation of some importance in a frequent stringent guarding of early virginity. Young maidens were quite commonly put under taboo for first use by the chief, after possession by whom all restriction ceased. No sense of a sacredness in chastity seems to have been involved in this, nor any sense of profanation in the contrary. It was only the thought of a special choiceness in an article that was fresh and unused. In the tremendous disturbances of life ensuing upon the advent of the white man, even this solitary restriction perished."

The effects of syphilis upon a race hitherto free from sexual diseases were simply murderous—multitudes perished, and those who escaped death were left with shattered frames and enfeebled constitutions which made them an easy prey to maladies of a trifling character. In addition to the original "stocking" of the island with syphilis by Captain Cook, a fresh increment of infectious material was from time to time added by the hordes of reckless sailors from the whaling vessels which were accustomed to visit the islands for recruiting purposes. No other race in the world, perhaps, has been so completely saturated with syphilis as the Hawaiian, and the syphilographer has here the opportunity of studying the strange mutation which the syphilitic virus undergoes in its transplantation to a virgin soil, and by which it acquires an added virulence and a greater potentiality for mischief.

He has also here an admirable field for studying the effects of hereditary immunity, which has resulted in the production of a much milder form of the disease in the course of three or four generations. At the present day syphilis in the Sandwich Islands is comparatively a benign disease, and furnishes but a small contingent to the sum of mortality. Almost all of the cases that came under my observation at the Queen's Hospital, in the Honolulu Dispensary, and elsewhere, were of the mildest type, the lesions being superficial and comparatively insignificant. Not only has the disease moderated in severity, but, according to the testimony of numerous physicians with whom I conversed, it has materially decreased in frequency.

Especially was I struck with the absence of notable evidences of hereditary syphilis among the younger population. Although I was constantly on the lookout for indications of hereditary taint, nowhere did I observe the characteristic impress of inherited disease, except among the lepers at Molokai. The comparative rarity of hereditary transmission may be explained by the fact that the Hawaiians of to-day are a sterile race. In some of the districts the percentage of births does not exceed 2 per 1,000, instead of 28 per 1,000 as it should be to balance the mortality rate. This is in striking contrast with the prolificness which distinguished the Hawaiian families in the olden times. What measure of influence syphilis has exerted in sapping the procreative powers of the people cannot be definitely determined. It is a singular fact that the loss of procreative capacity seems to be limited to the male, and is attributed to early indulgence in sexual excesses. Native women united to foreigners commonly bring forth a numerous progeny.

The fact that so few living children are born to Hawaiian families is probably due not so much to the impotence of the male as to the common practice of abortion. Before the advent of Christianity infanticide was the bane of the race. In the olden times the parents were considered the arbiters of the lives of their offspring, and the practice of strangling or burying alive their infants carried with it no conception of criminality. Thanks to the efforts of the missionaries, they have abandoned this practice, and now they resort to methods more in accordance with civilized customs. Instead of granting the product of conception a reprieve of nine months, they hasten its execution. One of the first lessons a Hawaiian girl learns on arriving at puberty is the expulsion of the fœtus. An interesting chapter might be written upon the various methods and agencies employed for this purpose; some of them are quite unique, and show the inventive genius of the native—such as stuffing the vagina with leaves or foreign substances of an extremely irritant nature. One of the most effective and commonly employed is drinking a decoction made from the roots of the pandanus-tree.

In this connection it may be said that, barring venereal diseases, the Hawaiian women are singularly free from the vast complexity and variety of uterine troubles with which their more civilized sisters are afflicted. As I learned from Dr. Trousseau, to whose extensive knowledge and experience of the Hawaiian people I am indebted for many facts of interest, native women seldom suffer from uterine displacements, lacerations, leucorrhœa, etc. This is somewhat surprising, in view of the fact that active horseback exercise is almost universally indulged in, the women always riding astraddle, man-fashion.

The process of parturition is attended with little suffering, and is usually of short duration. The presence of a doctor is rarely required, and then only in the presence of some grave complication. Women are confined usually in a sitting posture, the perineum resting upon a low, somewhat conical support. If the labor is not promptly accomplished the process is expedited by a native woman,

who kneels or sits behind the sufferer, and, encircling her arms around the abdomen, gives material assistance by more or less judicious pressure. The after-birth is expelled in the same manner, which rivals the Credé method of expression in ease and certainty. The woman usually gets about the same day, her first act being to wash the clothing soiled by her confinement; the accomplishment of this duty is, to the native mind, invested with something of the sacredness of superstition.

Honolulu boasts of a number of charitable institutions. The Queen's Hospital has one hundred and twenty beds, and is most admirably arranged and well kept. Its beautiful situation, cool corridors, and clean wards give it a most inviting aspect. A tax of two dollars per capita is levied upon everyone who visits the islands for its support. It is free to Hawaiians. White foreigners pay from fifty cents to two dollars and fifty cents per day for accommodations. Through the courtesy of Dr. McKibbin, the surgeon-in-chief, I saw many cases of interest, both in the medical and surgical wards.

But the chief interest of these islands to the medical man centres in the leper settlement of Molokai. Nowhere else in the world can be found a parallel to the extraordinary development and rapid spread of this disease, which in the short space of little more than one generation has attained such alarming proportions, and proved such a terrible menace to the public health.

In closing this letter I may incidentally mention a matter which will be of interest to those acquainted with the attempt made, some five years ago, to smirch the fair professional fame and personal integrity of one of the most honored members of our profession.

It will be remembered that a charge was made before the Academy of Medicine, that Dr. Barker had made a false claim to a Paris diploma. At Dr. Barker's request, a committee was appointed to examine this charge. After a thorough investigation, the committee made a unanimous report, declaring the charge to be unfounded and vindicating Dr. Barker, and their report was unanimously adopted by the Academy. And now comes, in a most singular way, and from a most authentic source, additional evidence of the utter falsity of this charge.

Dr. George H. Trousseau, to whom I have alluded, is the son of the famous Trousseau, of Paris, and inherits many of the brilliant and admirable qualities of his distinguished father. In giving me some reminiscences of his former life in Paris, he mentioned having met Dr. Barker as a guest at a dinner given by his father in Paris, and distinctly recalled the fact of his father having mentioned on this occasion that the diploma of the Faculté de Médicine had been conferred upon Dr. Barker. He also declares that he not only *saw* the diploma, but that, at his father's request, he personally carried the document to Dr. Barker's hotel and left it there, to be delivered to him upon his return.

It was a matter of great regret to him that he had not heard of the charge against Dr. Barker until many months after it was brought before the Academy, and thus had not the opportunity to refute it, which he would gladly have done. This direct statement, coming unsolicited from such an undoubted source, although not necessary to Dr. Barker's reputation, will be pleasant to his numerous friends.

HONOLULU, March 14, 1889.

THE INJURIOUS EFFECTS OF COCAINE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Dr. Windle's experience with cocaine corresponds in many respects with my own, in a more prolonged use of it in my own person, for the relief of a severe pressing pain caused by an intra-nasal deformity, since entirely cured by a removal of a portion turbinated by Dr. F. H. Bosworth. It was used for a year or more, in the form of spray, at different intervals.

Insomnia and loss of appetite were always present as long as any of the drug was in the system, but soon became normal on its suspension. The most noticeable reaction was in the nose itself, always in the form of increased hyperæmia, the more marked the shorter the interval between times of using it; slight if two weeks elapsed, but severe if used for several days in succession, even to the utter occlusion of the nares, so that no air could be forced through them. This would pass away in twenty-four to forty-eight hours. But the worst effect is on the nervous system. I think it must be on account of the proximity to the brain, for I have injected it all over the body in scores of minor surgical operations, without ever noting the slightest untoward effect. I never experienced any of Dr. Windle's "delightful effects," though pain was always relieved for hours. On the contrary, a most extreme nervousness comes on, making one feel that he would do anything to forget himself. (I remember one day, when not very busy, of reading the whole German grammar through at one sitting.) The pupils become dilated, and the face assumes a changed, weird expression. This, too, subsides as soon as the drug is out of the system.

I am convinced that the prolonged use of cocaine in the nasal cavities is pernicious, tending to defeat the very objects for which it is often used.

A. A. ARMSTRONG, M.D.

FAIR HAVEN, N. J.

THE RELATIVE INFLUENCE OF THE PRIMARY AND INDUCED CURRENTS OVER MUSCULAR CONTRACTIONS IN PARALYSIS.

A REPLY TO DR. STARR'S CRITICISM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In his criticism on my paper "On the Effects of Electricity in Peripheral Nerve Lesions," read before the Academy of Medicine, March 21st, and published in your issue of April 6th, Dr. Starr speaks as follows: "Dr. Rockwell had said that faradism acted on the intra-muscular nerves, and these being paralyzed in peripheral lesions, faradism failed to produce contraction of the muscle; while galvanism, acting on the muscular fibres, did produce contractions. He claimed that such a statement of physics was absolutely erroneous. The reason why the faradic current did not produce reaction in the paralyzed muscle was that the interruptions were too rapid for the diseased muscle to respond. Make the connection slowly and contraction would follow. There was no difference between galvanism and faradism in this respect."

As no opportunity was afforded at the time, allow me now to correct the erroneous impression that must have been produced in the minds of some by these statements. When there is no rheotome attachment, the momentary impulse induced in a secondary coil through its proximity to the primary coil, undoubtedly exerts a more powerful contractile influence than if these impulses followed each other with infinite rapidity. But a single "make and break" does not constitute the faradic current.

It is the faradic current which fails to cause contractions in certain forms of facial paralysis, and that one cause, *but by no means the only cause*, of its failure to produce contractions is because of the rapidity of its interruptions, no one denies. I have always taught that between faradism and galvanism the difference is mainly in degree rather than in kind, although the difference in degree is so wide as practically to amount to a difference in kind. As to the fact that the faradic current stimulates the muscles to contract through its action on the intra-muscular nerve-endings rather than on the muscular fibres, there is not, as I am aware, any dispute. When Dr. Starr states that there is no radical difference between galvanism and faradism in respect to the production of muscular contractions, he is very much in error. No helix can be so constructed as to

bridge the difference in the degree of their power in this respect, and in certain cases of degeneration of nerve-structure, where the galvanic current still causes reactions, the single shock of the induction current fails, equally with the rapidly interrupted faradic current, to call forth muscular contractions. A. D. ROCKWELL, M.D.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 14 to April 20, 1889.

UNDER authority from the Secretary of War, conveyed by letter of the 16th ultimo from Division Headquarters, the post of Fort Lisseton, Dak., will be discontinued June 1, 1889. Headquarters Department of Dakota, St. Paul, Minn., April 8, 1889. Special Orders, No. 35.

SMITH, H. K., Lieutenant-Colonel and Surgeon. Reports address of New Army Building as at No. 39 Whitehall Street, New York City. April 18, 1889.

WILLIAMS, JOHN W., Major and Surgeon, died at Jackson Barracks, La., April 15th, at 5 P.M.

HAPPERSETT, JOHN C. G., Major and Surgeon, is relieved from duty at Willet's Point, N. Y., and ordered to report to the commanding officer at Atlanta Barracks, Ga., for duty as Post Surgeon at that point. Par. 12, S. O. 88, A. G. O., April 16, 1889.

EWEN, CLARENCE, Major and Surgeon, promoted to Surgeon, with rank of Major, to take effect April 15, 1889.

WOODRUFF, CHARLES E., First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Mackinac, Mich., and ordered to Fort Gaston, Cal., for duty. Par. 14, S. O. 86, A. G. O., April 13, 1889.

MCKEE, JAMES C., Lieutenant-Colonel. Leave of absence granted in S. O. 44, February 25, 1889, A. G. O., is extended seven days. Par. 11, S. O. 86, A. G. O., April 13, 1889.

POLHEMUS, ADRIAN S., Captain and Assistant Surgeon, is relieved from duty at Fort Gaston, Cal., and ordered to Fort Monroe, Va., for duty. Par. 14, S. O. 86, A. G. O., April 13, 1889.

APPEL, AARON H., Captain and Assistant Surgeon, is granted leave of absence for twenty-one days. Par. 1, S. O. 38, Headquarters Division of the Missouri, April 16, 1889.

Official List of Changes in the Medical Corps of the United States Navy for the week ending April 20, 1889.

BYRNES, JAMES C., Passed Assistant Surgeon, detached from special duty at Norfolk, Va., and ordered to the Chicago.

HEFFENGER, A. C., Passed Assistant Surgeon, granted leave of absence for six months, with permission to leave the United States.

LEACH, PHILIP, Passed Assistant Surgeon. Leave of absence extended six months, with permission to remain abroad.

LOUNDES, C. H. T., Assistant Surgeon. Ordered to Naval Academy, Annapolis, Md.

MCCORMICK, A. M. D., Assistant Surgeon. Detached from the Vermont, and ordered to the Chicago.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 20, 1889:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	8	4
Scarlet fever	446	56
Cerebro-spinal meningitis	4	4
Measles	153	15
Diphtheria	183	43
Small-pox	0	3
Yellow fever	0	0
Cholera	0	0

ELECTROLYSIS OF THE EUSTACHIAN TUBE.—Drs. Cumberbatch and Steavenson report in *The Lancet* of November 24, 1888, a number of cases of obstruction of the Eustachian tube relieved by electrolysis. The instruments employed consist of a vulcanite Eustachian catheter and an electrical bougie. The bougie is made of a number of fine copper wires about seven or eight inches long, insulated by vulcanite to within an eighth of an inch of their ends. The ends of the wires are soldered into a nickel-plated metal cap. The bougie is small enough to pass along the catheter, and exceeds it in length by about one inch. The handle end of the bougie is provided with a binding screw, to which the insulated copper wires are also attached, for the purpose of connecting a rheophore from the battery. On this end of the bougie an inch is marked off divided into eighths. Each eighth of the inch passes into the catheter as one eighth protrudes at the other end. It is therefore possible to tell, when the catheter is in the orifice of the Eustachian tube, how much of the bougie is in the canal. On the catheter there is a metal ring, or some other mark, as in all catheters, to indicate the position of its end when it is being inserted. The operation is performed in much the same way as the electrolysis of the other mucous passages which has recently been described. A pad connected with the positive pole of a battery is moistened and placed at the back of the patient's neck. The Eustachian catheter is then passed along the nostril into the tube, and the bougie, already attached to the negative pole of the battery, is passed along it as far as it will go, until it meets an obstruction. The circuit is then closed. A galvanometer should be included in some part of the circuit, and the strength of the current increased until a strength of four milliampères is obtained. A frizzling noise will be heard by the patient in his head, usually likened to the frying of fish; and the operator, by approaching his ear to the catheter, can hear the crackling produced by the frequent breaking of minute bubbles of gas. The electrolysis is kept up for four minutes, and usually before the expiration of that time, if it is possible that the obstruction can be removed, the bougie can be pushed on for a small distance, sometimes for its full length. Generally, on the first occasion the Eustachian tube is rather sensitive, but it seems to acquire toleration for the process, and at no time is so much discomfort experienced as might be expected from setting up chemical decomposition in the middle of the head. The authors state that they have met with no unpleasant experiences in a number of cases thus treated, nor have the patients ever complained of more than very temporary discomfort. In those cases in which the deafness was due to a simple obstruction of the Eustachian tube, the results obtained were, it is claimed, most encouraging.

STERILITY IN WOMEN.—Dr. Parvin says that ordinarily one woman in eight is sterile; but in women who have fibroids, one in three is sterile.

THE MANAGEMENT OF HIP-JOINT DISEASE FROM AN ANATOMICO-PATHOLOGICAL BASIS.

BY A. M. PHELPS, M.D.,

NEW YORK.

THE diversity of opinions in the profession as regards the management of morbus coxarius has led me to present this paper upon that subject to-day. The plan of treatment advocated by many of the American orthopædists is extension by means of some form of portable apparatus which allows of free motion of the diseased joint during locomotion. But all, with an occasional exception, appear to unite upon the idea that extension is the first principle in the treatment. By extension of a joint we do not mean that the joint surfaces are separated, but that intra-articular pressure is relieved, and the joint protected from the trauma due to reflex spasm of the muscles.

Opposing this idea are Thomas and his followers, who believe that the joint should be absolutely immobilized, that the patient should never be allowed to walk upon the apparatus, but use crutches, and that all forms of extension apparatus are entirely useless. And then we have the third school, who believe that the disease is *constitutional*, and who advocate the use of local applications—constitutional treatment, fresh air, etc.—paying but little attention to the mechanical treatment of the joint.

It seems to me that those who have carefully observed tubercular inflammation of this joint or its appendages will have been convinced that the spasmodic action of the muscles is a very important element in producing the destructive changes which so frequently and so generally follow in joints not treated.

Thomas denies that there is spasm of the muscles about the joint. The American surgeons seem to be pretty generally convinced that spasm of the muscles always occurs. I believe that all cases of hip-joint disease are attended with spasm of the muscle; that the spasmodic action of the muscles produces great intra-articular pressure; that the trauma resulting is the chief factor in producing destruction of the joint. Volkman, Albert, and Koenig demonstrated that inflammation of the hip-joint begins as a simple inflammation, either in the soft parts or the bony structures, subsequently becomes tubercular by inoculation, then purulent; in other words, nearly all joint affections of a chronic nature are tubercular. The idea that *tuberculosis of joints is a local disease due to accidental inoculation and not to a constitutional or strumous condition, which means nothing, I most heartily indorse.* The irritation of the peripheral extremities of the nerves in or about the joint produces spasm of the muscle, the spasm of the muscle in its turn destroying the joint by trauma, aided by the rapid reproduction of the bacilli of tuberculosis; moreover, that if these cases of chronic tubercular joint diseases are perfectly immobilized and the intra-articular pressure removed, nature will take care of the tuberculous material, and the same results should be attained in hip-joint disease as in that of the knee. Bone abscesses will become arrested, or, if they do rupture into the joint, the quantity of pus will usually be limited.

Those gentlemen who advocate the constant moving of the joint during inflammation argue that anchylosis will certainly follow unless motion is kept up. Thomas, of Liverpool, says that anchylosis is more certain to follow if motion is allowed, and that an inflamed joint is not so likely to anchylose if absolutely immobilized; that the anchylosis which follows is produced by the severity of the inflammation, and not by immobilization.

Many also teach that healthy joints will become anchylosed if immobilized for any considerable period. In answer to them I will say that I have immobilized inflamed hip-joints from ten months to a year and a half without producing anchylosis; that I have also immobilized healthy joints in animals from six weeks to four months without producing anchylosis, as these specimens will illustrate. (Specimens were shown of joints of dogs immobilized in the Loomis Laboratory for four months by means of plaster of Paris, which to all appearance were normal.)

Two cases of morbus coxarius were presented, one of which had been secured in a Sayre wire cuirass for eight months without movement. The hip-joint was found freely movable. The other case was one of extensive abscess of the hip-joint, which had been freely opened and washed out. The boy had been fixed in the portable bed for five months, the joint being kept perfectly at rest. The joint was freely movable, and but little pus discharged from the sinus, perhaps two drachms in one week.

Where abnormal intra-articular pressure is present there is danger of destruction of the head of the bone even in a healthy joint, as is illustrated by this specimen which I hereby present. The hind leg of the dog was fixed over his back with plaster of Paris in a cramped position. At the end of six weeks he was killed and the hip-joint examined. The head of the bone and acetabulum were red and congested, and the cartilage was commencing to disintegrate. The knee-joint, in which no intra-articular pressure was made, was found normal.

To the gentlemen who argue that motion should be permitted in an inflamed joint, I will say they seem to forget that one of the laws of surgery is that where a part is inflamed it should be put at rest whether it is muscle or joint, or any other part of the body that can be immobilized. By constantly moving the joint the delicate new tissue which nature is trying to produce is broken up, which may lead to destruction of the joint, either by necrosis, anchylosis, or cicatricial contraction of the capsule.

The spasm of the muscle is due to reflex irritation of the peripheral extremities of the nerves supplying the bony or soft parts of the joint. The atrophy of muscle which follows I believe to be produced mechanically, the result of reflex contraction. The muscles of the leg in the dogs which were immobilized for three and four months were found to be extremely atrophied, although, as you have seen, no disease was present in the joints or bone. However, this is still an open question, Barwell believing it to be a true atrophy of degeneration due to nerve-disturbance. The atrophy is in proportion to the severity of the reflexes. The contraction of muscle is in proportion to the reflex irritation; the reflex spasm in proportion to primary irritation of peripheral nerves in or about the joint.

Reflex spasm is greater in bone disease owing to the greater pressure exerted upon the nerve-filaments, and much feebler when only soft parts are inflamed. Atrophy

of the muscle is frequently seen where no bone disease is present. It is more likely to follow bone disease on account of the severe reflex spasm. All the muscles about the hip-joint are more or less affected by spasm in inflammation. Those most notably affected are the abductors, adductors, and flexors. The spasmodic and rigid contraction of these muscles, together with the rotators, produces limited motion in hip-joint disease. The amount of contraction necessary to produce this limited motion causes great intra-articular pressure and leads to congestion and necrosis either of the head of the femur or of the acetabulum, the bacilli playing a secondary part and depending to a certain extent upon the constant irritation and local rise of temperature for their growth.

I fully agree with Sayre, Taylor, Barwell, Marsh, and

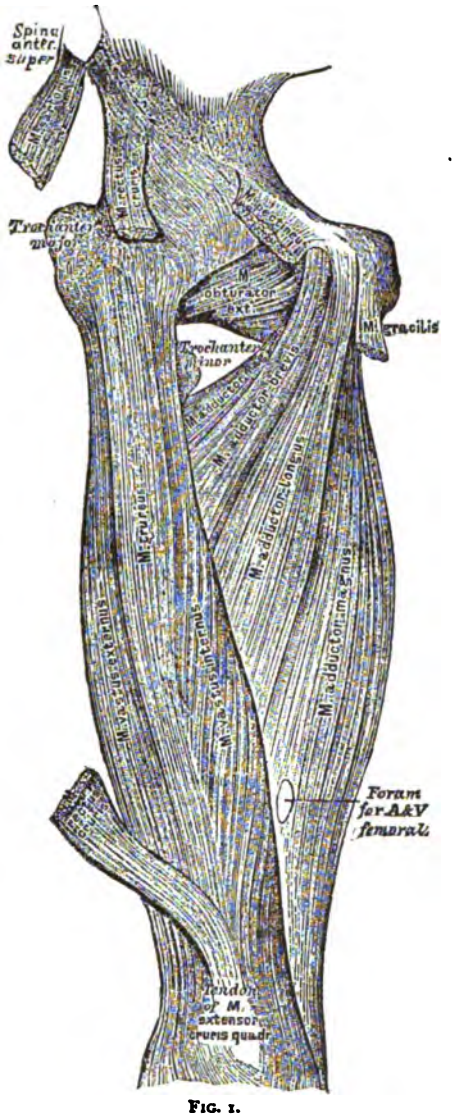

Fig. 1.

others, that spasm of the muscle should be overcome by extension. I also fully agree with Thomas, of Liverpool, that every joint should be fixed and absolutely immobilized until all inflammatory action has subsided and a cure effected. But I do not believe that immobilization of the joint can be accomplished without extension; neither do I agree with the first-named gentleman that extension immobilizes a joint sufficient to get the best results possible, but that a combination of the principles of fixation and extension should be the law. Hence the long traction splint which admits of motion does not immobilize, and the patient produces injury of the joint every time he steps upon it, as is evidenced, in the vast majority of cases, by the almost constant increase of the deformity after the splint is adjusted. Neither does a Thomas splint produce extension; hence there must be abnormal intra-articular pressure when spasm or contraction of muscles is present which must produce congestion of the head of the bone. And then, if extension is to be applied it should be in the direction opposite to the line of traction made by the muscles. In other words, to apply extension to a hip-joint we should not only make traction in the line of deformity but also in a line at right angles to that deformity. In other words, to relieve perfectly intra-articular pressure extension must be made in a line corresponding to the axis of the neck, and not with the axis of the shaft, for the following reasons: The adductors and abductors pass from the femur diagonally across the body to the pelvis, as Figs. 1 and 2 will demonstrate. These, with other muscles, are the ones affected by spasm. When they contract the head of the bone is drawn firmly into the acetabulum, the force operating on a line corresponding to the axis of the neck. The flexors act on a line corresponding to the axis of the shaft.

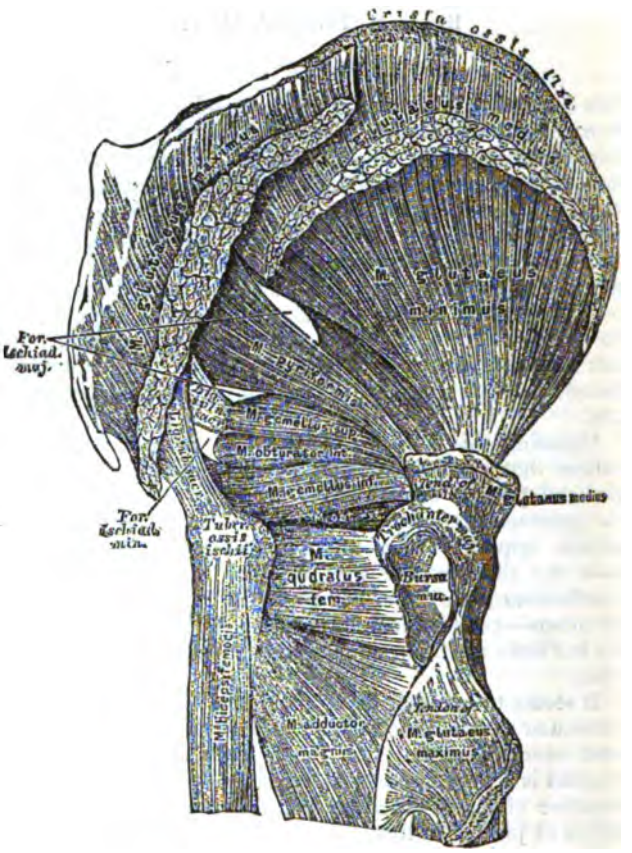

Fig. 2.

No apparatus has heretofore been devised which will so perfectly fix a hip-joint as double extension in bed—the body and well leg fixed to a long splint—first recommended, I believe, by Dr. Sayre (see Fig. 3). The slipping of the bandages proved to be a nuisance. This led me to substitute the plaster of Paris, which meets every requirement. The splint should extend to the axilla. The diseased limb should be held in the deformed position during its application, that the body and healthy limb may be in a normal position. The jury-mast is adjusted only in cases of spinal caries, cervical or dorsal.

The treating of a case in bed for a long time I do not believe to be good practice. But during the active stage of hip-joint disease, whether it is in the first, second, or third, the patient should be put to bed with the two lines of extension and fixation dressing until the active symptoms and deformity have entirely disappeared, and the spasm of the muscle is no longer present. Then, in small children, they should be put into a Sayre's wire cuirass, or the portable bed with the two lines of extension, such as I show you here (Fig. 4).

A board is cut to correspond to the length and width of the child (Fig. 5). This is carefully padded. The child is now laid on the board and enveloped with a

plaster-of-Paris bandage from the feet to the axilla to a thickness of three-eighths of an inch. When the plaster is set the front is cut away. This bed can now be lined and a front put on it and lacings put in, or the child can be held in place by means of bandages. As the plaster bandages are rolled on they should be nailed to the edges of the board, thus making the board and plaster one. This bed will be found to fit better, be much lighter, and more convenient to make than the wood cuirass.

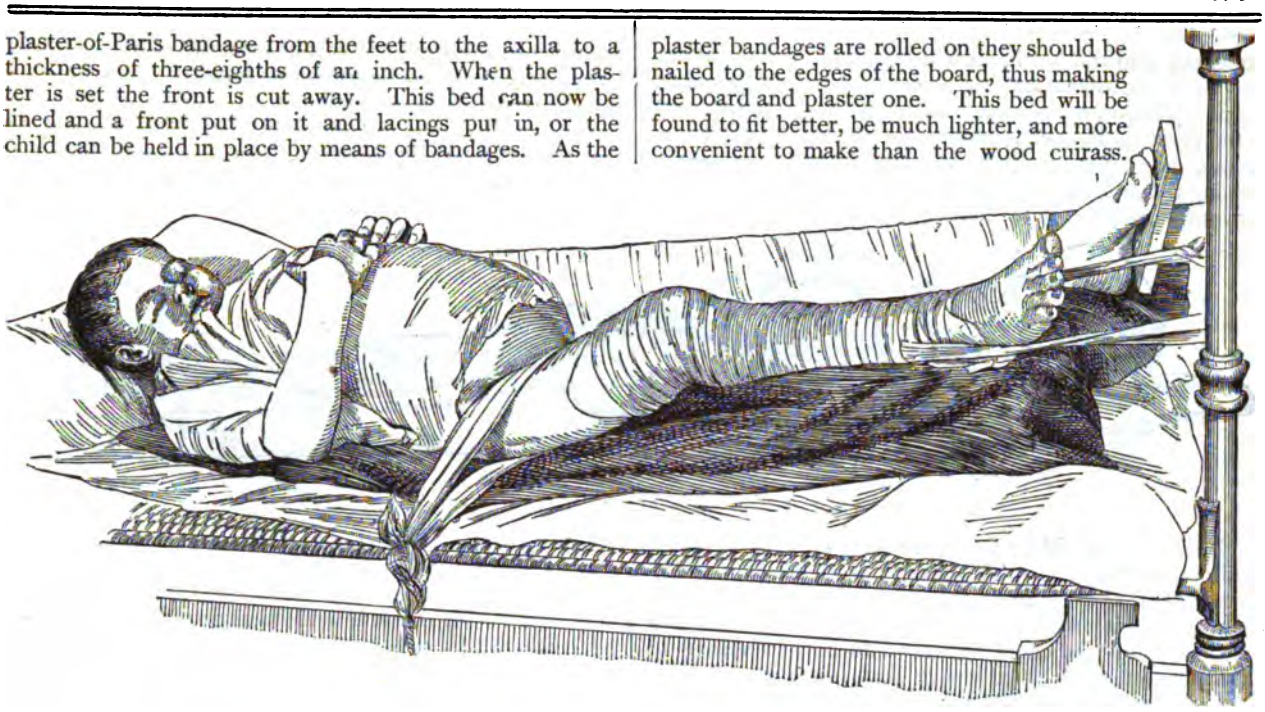

FIG. 3.

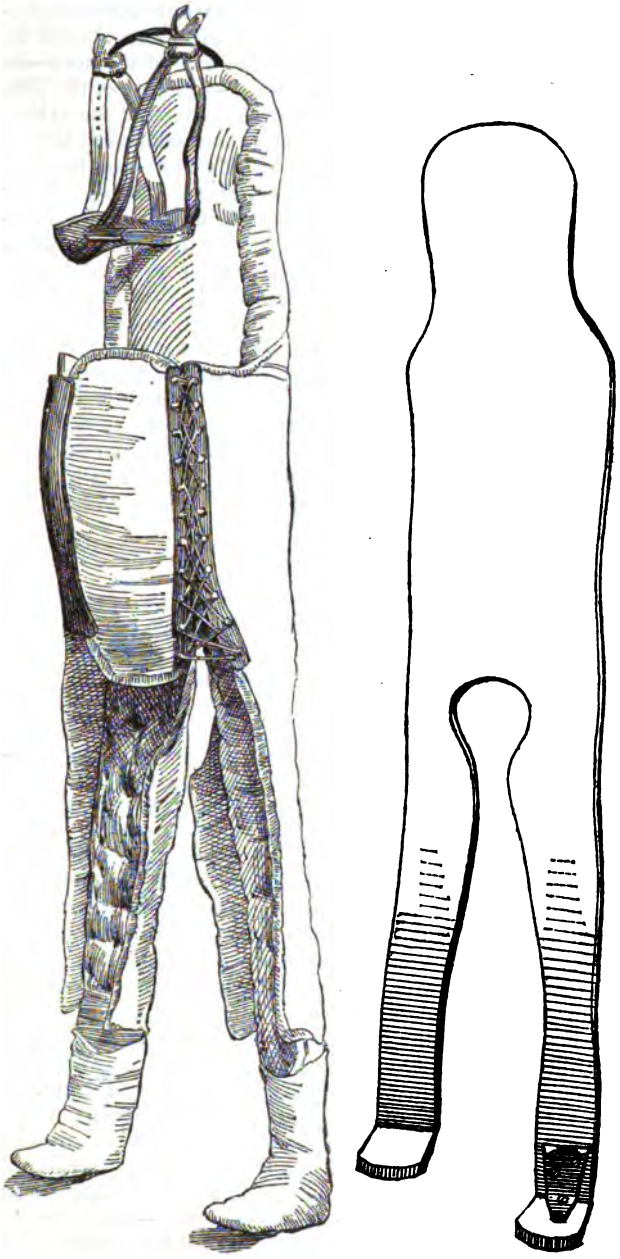

FIG. 4.

FIG. 5.

Extension is made to the foot-piece, and lateral extension by cutting away the side a little and putting in a staple (see Fig. 6, to which the bandage is tied).

The portable bed possesses nothing superior to the wire cuirass to recommend it; only its cheapness, costing, as it does, about three dollars, and then a skilled mechanic is not required—any practitioner would be equal to the task. This will enable the mother or nurse to carry the child about, and the hip joint is perfectly immobilized by fixation and extension applied in the proper lines. After the storm has passed and the legs are parallel, then a splint such as I here present can be applied, putting the patient upon crutches, with a high shoe on the well leg, or when he is convalescent allowing him to walk upon this hip-crutch. (Figs. 7 and 8.)

Every stage of hip joint disease should be treated precisely the same, with certain modifications, beginning the treatment in bed, applying extension and fixation as previously described until the two limbs are parallel, and as long as muscular spasm and evidences of active inflammation are present. No hip-splint should be applied in bed, because it does not so perfectly extend and immobilize the joint as the means which I have just described. All abscesses should be incised, cutting them their entire length, scooping them out thoroughly, putting in drainage to the point of disease, and entering the joint if the disease is to be found within the capsule; in fact, thoroughly washing, scooping, and cleaning out the joint. A large number of abscesses of the hip-joint are absorbed, but from the fact that one can never tell, but simply give a lively guess as to which abscess will burrow and form sinuses leading to the consequences of pus-absorption, I believe that it is a better rule to operate upon every abscess, noting an occasional exception. When the operation is performed with strict antiseptic precautions, the operator's hands thoroughly cleansed, the skin carefully washed and shaved, the instruments sterilized by boiling for fifteen minutes before the operation in an antiseptic solution, and the dressing and catgut perfectly antiseptic, a rise of temperature following the operation will seldom be seen, but, on the contrary, these patients will take their first meal for weeks after an operation of the kind.

If the advocates of the non-operative interference of these abscesses will designate to us which abscess will be absorbed and which will produce bad results we will cease operating upon such abscesses as will be absorbed, but so long as that line is not drawn, and knowing perfectly well that quite a considerable per cent. of the cases of hip-joint disease die from pus-absorption and its con-

sequences, and that no harm will ever follow the cutting for pus if the operation is properly performed, whether it is in a joint, in the muscles, in the eye, the brain, or any of the great cavities of the body, we should continue to operate as we have in the past. Another advantage—by opening the abscesses the joint can be carefully and intelligently explored with the finger, and frequently the tention of the capsule by pus or synovial effusion should be relieved either by aspiration or incision; then the traction forces will not produce pain.

To conclude, my observations lead me to believe that the most serious element of destruction in hip-joint disease is the trauma and pressure produced by the spasm of the muscle; that tubercular will recover as surely as non-

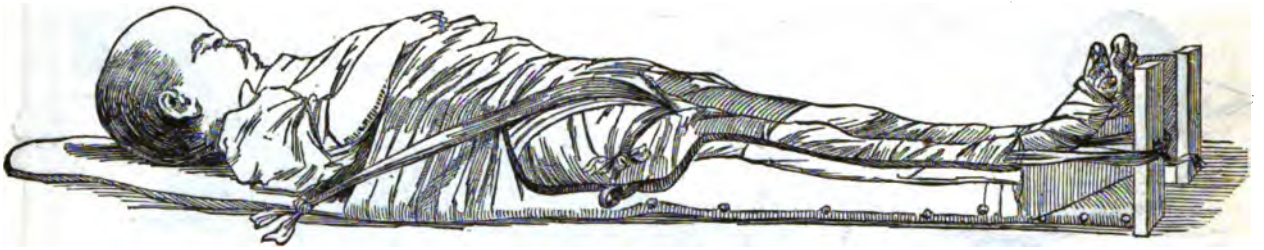

FIG. 6.

head of the bone will be found separated from the neck and loose in the joint. This should be removed, thereby rescuing the patient from the danger of "artificial excision," of which we so frequently hear. Hip-joint disease should also be cured without deformity excepting in cases characterized by extensive bone disease. Patients in whom deformity exists, unless proper extension does not overcome it, should be at once operated upon, either subcutaneously or by open incision, and such tissues divided as will allow the limb to be replaced in a normal position.

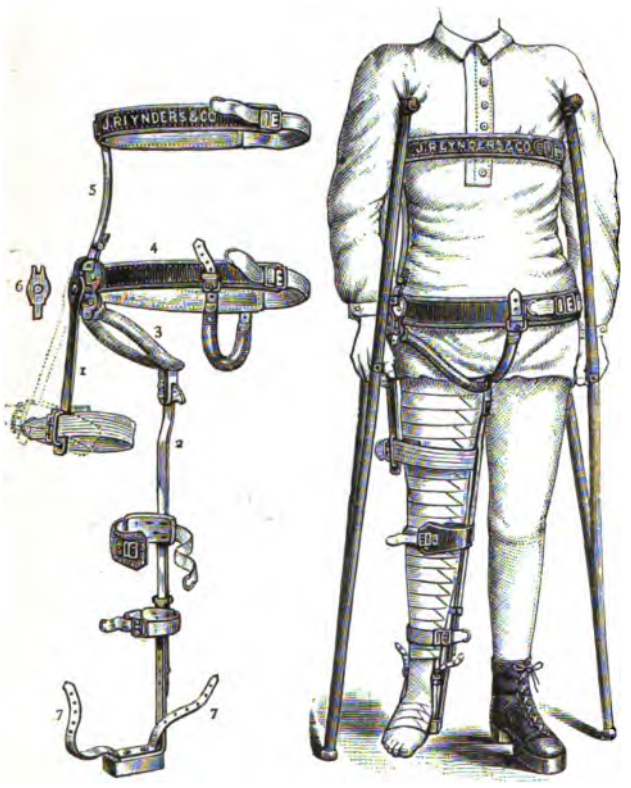

FIG. 7.

FIG. 8.

Fig. 7 represents the perineal crutch with the abduction bar (1) adjustable by means of the key (6), for the purpose of making lateral extension. The steel bar (2) is adjusted to the steel ring (3), which makes a firm crutch, the pressure coming on the tuberosity of the ischium. Adhesive straps extending to near the body from the ankle, furnish means of extension by tightly buckling them to the straps (7, 7), the ring (3) furnishing counter-extension. The rod (5) ending in the upper ring prevents flexion and extension of the legs. The whole splint is intended to prevent every motion at the hip-joint, and at the same time apply extension in a line with the neck of the bone. Fig. 8 shows the crutch and splint adjusted, the patient using crutches, and standing on a high shoe upon the well leg.

Cases of false or true anchylosis of the hip at a bad angle are better corrected by osteotomy through the lesser trochanter. Cases of dislocation should be excised, or osteotomy performed, when subcutaneous division of the muscles will not readily overcome the deformity.

When operating upon abscesses all dead bones should be removed. If the neck and head should be found diseased excision should be most certainly performed. Distubercular joints, if the spasm of the muscle is overcome; that fixation of the joint without extension is an impossibility; that the successful treatment of the joint must depend upon its absolute immobilization, which can only be produced by proper extension and fixation; that the constitutional treatment of hip-joint disease amounts to but little, independent of mechanical treatment; that the mechanical treatment is everything; that extension in a line with the axis of the shaft and deformity alone in hip-joint disease is entirely wrong; that extension should be made in a line corresponding to the axis of the neck—in other words, two lines of extension—otherwise, the idea of extension is not perfectly carried out; that anchylosis of the joint is not produced by its immobilization, but by the severity of the inflammation; that the long traction hip splints in general use neither properly extend neither do they immobilize the joint; that the intra-articular pressure results in the destruction of the joint or anchylosis in the majority of cases; that the results of hip-joint disease should be as good as those of knee-joint disease and will be, provided perfect immobilization can be carried out; that the surgical law in regard to abscesses should not be violated in the treatment of abscesses of the hip-joint; that nearly all cases should be treated for a time in bed; that when the limbs are parallel and the active symptoms have subsided the hip-crutch can be given adults with crutches, and children the portable bed, and, finally, after convalescence, the hip-crutch, either with or without the high shoe and crutches.

THE THERAPEUTIC VALUE OF SYSTEMATIC PASSIVE RESPIRATORY MOVEMENTS.[1]

BY HENRY LING TAYLOR, M.D.,

NEW YORK.

THERE is little doubt that the specialization of occupations and pursuits which is such a marked feature of modern civilized life, notably in our cities, has been in some respects a detriment to our physical development. If the hand worker is now less frequently starved outright, he is perhaps more often deprived of sufficient light and wholesome air, and his physical and mental activities restricted to a narrow range. In the commercial and head-working classes excessive competition stimulates, and often necessitates, a war of wits, which is usually associated with sedentary habits, and frequently results in starvation of the tissues, in a spindling or flabby physical type, diminished fertility, and stunted asymmetrical offspring. When we come to analyze it, we find that modern city life among all classes, in spite of much superficial variety, is characterized by nothing so much as narrowness if not monotony, and this is as true of the leisure classes as of any. What can possibly exceed in inadequacy of neuro-muscular

[1] Read before the Section on Theory and Practice, of the New York Academy of Medicine, March 19, 1889.

experience the routine activities of a man or woman of fashion? Probably nothing; but many of our professional and business men working in narrow grooves, under continuous strain, and innocent of the rudiments of a common-sense hygiene, many of our over-worked women and high-pressure children certainly run a good second.

Important regions of the body, as the shoulders, back, and loins, and especially the chest, with the thoracic and abdominal viscera, suffer from our restricted and feeble muscular experiences, with the result of diminished neuro-central tone and general vigor, and it seems to me we frequently have a combination of restriction and irritation, well calculated to produce one-sided and unwholesome, instead of well-rounded and robust, development of the organism. There are always feeble individuals, and competition is always hard on the feeble; with increased friction we must get increased detritus.

Flat and narrow chests, and diminished respiratory power, with feeble vital energy and small endurance, are the frequent expression in the second generation of imperfect circulation, assimilation, and innervation, the result of deficient, one-sided, or strained activity in the parents. Thus we can conveniently group for purposes of study and treatment those conditions resulting from, or dependent on, deficient chest aspiration. The condition of deficient chest power has long attracted the attention of physicians, and many efforts have been made to develop chest capacity and to increase respiratory efficiency, by gymnastic exercises, especially of the upper extremities, by voluntary attempts at deep breathing, by modifications of air-pressure, and by other means.

All things considered, a prolonged out-of-door life, combined with moderately active but varied exercise in the open air, probably furnishes the best remedy for many of the cases we are considering.

Systematic gymnastic exercises, as usually given, are far from satisfactory for this special object. They are not adapted to the weak and feeble, and they are open to the objection that while pulse and respiration are considerably accelerated the conditions are not favorable for thorough lung-expansion. In order to pull, push, or lift with the arms, the breath is instinctively held in order to immobilize the thorax, which is the fixed point from which the shoulder muscles work under these conditions. This is a fundamental difficulty, and, as a matter of fact, we notice that boxers, oarsmen, athletes, and porters, who are characterized by great muscular development about the chest, are frequently round-shouldered and of poor endurance. Measurements are easily increased by piling up muscle on the thorax without necessarily increasing respiratory capacity. Dr. Stanton Allen tells me that a well-known gymnast in this city, who has a chest expansion of ten inches, and enormous muscular development, blows less on the spirometer than before he developed his muscles, and that the same has been noticed in some of his pupils. Of course, gymnastic exercises will increase chest measurement by overlaying the thorax with muscles, and probably in most instances, if judiciously used, real chest expansion will follow from the increased demand, but there will always be the objection I have named in using it in sick people, or primarily for chest expansion. I believe that it may produce chest contraction if injudiciously employed.

Voluntary deep and measured breathing can without doubt accomplish something, but its application is much restricted by its irksomeness and the fatigue it produces. Let anyone take forty or fifty successive full inspirations and he will find it very tedious and very tiring work.

I can conceive that the respiratory efforts which accompany the inhalation of gases, now systematically practised for various purposes, only have some value as a respiratory exercise. Is it not possible that certain much advertised nostrums may be kept alive by the fact that the method of administration involves an imperfect respiratory exercise?

Is there, then, any method by which we can expand the chest freely and regularly, for considerable periods, without undue fatigue to the patient? any way to automatically stimulate this automatic function?

Among the exercises based on the Ling system, which my father used on beginning practice in 1856, and which will be found figured and described in his book,[1] is one where the patient is seated, while the operator, standing on the bench behind him, lifts up the shoulders with the hands under the axillæ; one of his knees supports the patient's back, which is arched backward to produce full inspiration. In another movement the operator, standing as before, grasps the patient's hands and pulls the arms upward and backward against his resistance, after which the patient pulls down the hands of the operator until they lie in front of the chest;[2] this was also given as a purely passive movement, like Sylvester's artificial respiration. These and similar movements were very much used for many years in his practice to increase chest expansion and as a general tonic. Very soon Dr. Taylor began to substitute for the hand of the operator, in many of the active movements, a graduated mechanical resistance, and about 1872 he devised apparatus by which the most important passive movements were given by steam power, among them the passive respiratory movement I have mentioned. This apparatus, called the "respirator," has been in constant daily use since then, and has proved itself a most valuable therapeutic aid, far exceeding the old hand-method in efficiency. We use two respirators, one giving thirteen and the other sixteen full respiratory movements a minute, and the strength of the pull can be exactly regulated. The movement is a purely passive one, except that the handles of the apparatus are grasped by the patient. The patient is seated on a reclining couch, the main levers, bearing the handles, pull the arms of the patient strongly upward and backward, while the chest is arched by the simultaneous backward movement of the upper part of the back of the couch. The main levers are, for most purposes, so adjusted as to slightly raise the patient from his seat at the limit of motion, after which they move downward and forward, allowing the arms to drop by the sides, and the upper part of the back of the couch swings forward on its hinges, to favor expiration. The exercise is given for from ten to thirty minutes at a time, or with the more rapid machine from one hundred and sixty to four hundred and eighty full regular inspirations and expirations at a visit. The respirations of the patient coincide automatically with the movement of the machine.

The actuating mechanism of the respirator consists of two eccentrics symmetrically placed on a counter-shaft; these operate two cranks, to which the long L-levers carrying the handles are pivoted in such a manner that the pivots can be shifted on the crank and lever, and the extent of the stroke increased or diminished at will. The eccentrics also operate the levers which give motion to the adjustable back of the couch. The machine is stopped by shifting the belt to a loose pulley.

Theoretically we should expect, as physiological effects from the use of such a passive exercise, increased oxygenation of the blood and elimination of respiratory waste; increased thoracic capacity and power; better venous return on account of increased thoracic aspiration, and a decided effect on the higher nerve-centres, from improved nutrition and circulation, as well as from direct impression on the centres.

I am indebted to Miss Aimée Raymond for a series of careful observations on the pulse, respiration, and temperature of several patients who were taking the respirator about half an hour daily. In four patients, all the subjects of lateral curvature of the spine, the number of observations was eight to thirteen each. To study the varying results, I took the averages, which I append, disregarding fractions, in the following table:

[1] Theory and Practice of the Movement Cure, 1860.
[2] Op. cit., pp. 216, 217, ed. 1864.

TABLE I.

	Average	Pulse before.	Pulse after.	Temperature before.	Temperature after.	Respiration before.	Respiration after.
Miss M——, aged sixteen; respirator one-half hour.	13 days.	92	90	98.1	98.3	24	24
Miss B——, aged seventeen; respirator one-half hour.	11 days.	94	92	98.7	98.8	27	25
Miss W——, aged eighteen.	13 days.	85	87	98.2	98.8	18	18
Miss L——, aged fourteen; respirator twenty minutes.	8 days..	88	90	97.9	98.0	20	19

From this it is seen that in the two with the slower pulse an increase of about two beats was noted, while in the two with the more rapid pulse a decrease of the same amount followed the use of the respirator. In two the respirations remained at the same rate after the exercise, and in two they were slightly diminished in frequency. In every one of the four the average temperature under the tongue was found slightly increased after the exercise —the general average being 98.2 before exercising and 98.4 after—due, as I take it, to increased oxidation.

We notice, clinically, that the circulation improves. The cerebral centres are soothed and the patient frequently becomes drowsy under the repeated effortless stimulation of the centres, for we must not forget that we have here a direct means of stimulating certain centres. After the exercise the patient usually feels invigorated, and the chest feels fuller and more expanded. If there has been mental or physical overwork the patient feels refreshed from the more perfect oxygenation of the blood, and the exercise of neuro-muscular arcs habitually neglected, while at the same time the overworked areas are at rest.

After a course of the respirator we usually find improved color and circulation, often improved appetite and digestion where these are at fault, and usually some increase in weight when the patient is thin. In nervous patients, better sleep and better co-ordinated neuro-cerebral action often follow.

The effect on the chest expansion is usually quite marked after a few weeks, sometimes after one or two. The respirator has been most frequently given, not so much for its special effect in developing chest expansion as for its effect on the circulation and as a general and special tonic. But during the last five or six years

TABLE II.

No.	Sex.	Age.	Date.	Chest, inches.	Date.	Chest, inches.	Number of months.	Gain, inches.
1.	M.	14	Oct. 11, 1883	27½–30¾	Nov. 13, 1883	27½–31¼	1	¼
2.	M.	16	Oct. 11, 1883	27½–31..	Nov. 13, 1883	27½–31¼	1	¼

14..	M.	18	April 4, 1888.. ..	31¾–33..	May 3, 1888	32–33½..	1	⅓

I have made, from time to time, a considerable number of careful chest measurements. I have taken fourteen cases without selection, except that cases of well-developed lateral curvature of the spine are not included (Table II.), and find that the measurements, after a month or two of the respirator—usually six times a week for from twenty minutes to half an hour a day—has produced an average gain of just about one inch in the chest measurement on full inspiration.

The patient often continues to gain in chest measure for a considerable time, even when the visits are much less frequent, but the rate of increase is not so rapid after the first two or three months. When the exercise is discontinued frequently some of the gain is lost, but a good deal is retained. In all of the fourteen unselected cases there was some gain at the end of the short period given. Whatever the amount of gain in chest capacity, there is nearly always marked improvement in health.

A lady, aged thirty-five, not included in the table, who was taking the respirator for its tonic action, told me that the waists which had always fitted her had become so much too small after a month of the exercise that she was no longer able to put them on, though she had not gained in weight. It should be remembered in considering these results that they were all obtained in delicate, or even sick people, with particularly deficient chest capacity. Chest measurements are subject to many inaccuracies, but we can, I believe, get useful information from repeated observations.

This exercise is particularly useful in cases of flat, narrow, shallow, weak, and inelastic chests, whether due to faulty development, phthisical predisposition, old pleuritic exudations, round shoulders, or other causes; but, valuable as it is in such cases, I believe that still greater benefit is derived from passive respiratory movements systematically employed in the actual physiological and clinical effect of the exercise, irrespective of its expansive power on the thorax.

Lateral curvature of the spine always diminishes respiratory capacity, and for this and other reasons I prescribe this exercise for such cases in connection with other treatment. Lateral curvature is one of the most difficult things to treat in orthopedic practice, and I do not claim to be always able to secure brilliant results, but I have noticed that whatever be the effect I am able to produce on the curvature, my patients almost invariably improve in health and vigor. The exercise is indicated in anæmia and in convalescence from exhausting disease. Another class of cases in which its use is followed by particularly gratifying results is that of the functional neurotics, ranging from anæmic, delicate, and overworked persons—women especially—of flabby fibre and feeble respiratory power, through the victims of backache, headache, the neuralgic, dyspeptic, and semi-uterine type, up to the well-developed neurasthenics and hysterics, even including the bed-ridden neurotics. This is a large and heterogeneous class of invalids, many of them very great sufferers, who should command our best skill and sympathy. In no class of cases is routine treatment of any kind less applicable. Each case must be treated and guided on its own merits after the closest analysis and discrimination of the conditions and indications. In nearly all, however, we need to improve the quality of the blood and the general health, and to regulate nerve-centre action. The respirator is one of the means at our command to fulfil these indications. For we have here (and this is only one of many exercises, but perhaps on the whole the most important) a means of directly affecting the nerve-centres as well as the circulation. We may begin with special exercises in bed, if need be, and after a time are able to add the passive respiratory and other passive movements in the exercise-room. This idea is perhaps the most fruitful of any in connection with the application of the respirator, but I have not time to develop it here. I refer those interested to a paper on "The Hygiene of Reflex Action," published last March in the *Journal of Nervous and Mental Disease*. I wish to call attention to the circumstance that the action of the respiratory and similar passive movements for the trunk and extremities have this in common with the use of massage, electricity, and hydro-therapeutics—all valuable when used for specific indications—that they act directly on the nerve-centres by peripheral stimulation. But I emphasize a marked difference in the kind of stimulation. The respiratory and similar movements are not a simple shock or stimulus, as

shown of stimuli, to the centres, but train and educate them in coherent associated movements by a series of changes in position and muscular tension of the arms, trunk, and thorax, and modify their tone and action by a series of impressions on the centres which react to changes in the respired air and circulating blood. Each has its appropriate indications and inherent limitations; I simply note a difference. There is an equally radical and important difference in the general effect produced by such exercises, and by gymnastics, which consists in the almost total absence from the former of voluntary or violent effort and consequent fatigue, rendering them applicable to the very weak and delicate. Here, too, each has its appropriate field.

The application of systematic, passive respiratory movements to the treatment of some forms of organic heart-disease, and to certain diathetic vices and faults of elimination where it might seem indicated, remains to be studied; but we have in them a tested means of—1, expanding and strengthening the chest, and invigorating the respiratory function; 2, oxygenating the blood; 3, equalizing and toning the circulation; 4, regulating and co-ordinating nerve-centre action; 5, improving general vigor.

201 WEST FIFTY-FOURTH STREET.

THE BEHAVIOR OF HYDROCHLORIC ACID IN THE STOMACH OF PHTHISICAL PATIENTS.

WITH A FEW REMARKS ON THE PRESENCE OF HYDROCHLORIC ACID IN SEA-SICKNESS.

BY MAX EINHORN, M.D.,

PHYSICIAN TO THE GERMAN DISPENSARY, NEW YORK.

As long as there is no specific remedy against tuberculosis, the sole treatment must resolve itself into one of strengthening. We must, first of all, consider how to feed the patient properly, and how to strengthen the organism.

It is therefore important to discover the condition of the digestive apparatus in phthisis pulmonum. The products of the stomach secretion are now easily obtained, and thus the condition of the stomach, in cases of phthisis, has been examined by Edinger,[1] already, in 1881. In several cases of phthisis pulmonum, which were accompanied by amyloid degeneration of the organs, Edinger did not find any hydrochloric acid in the stomach; in two of these cases there was a pronounced amyloid degeneration of the vessels of the stomach. Of a third case of phthisis Edinger[2] says the following: "In a third case of phthisis pulmonum, in which the autopsy showed vast amyloid degeneration of the liver, spleen, kidneys, and only a small degree of degeneration of the vessels of the stomach and intestines, the free hydrochloric acid was twice wanting in the fourth hour of digestion. . . . The question whether the absence or the diminution in the secretion of free hydrochloric acid in our cases is due to the degeneration of the blood-vessels, or whether it is caused by other conditions, especially by the high degree of anæmia common to all cases, cannot be answered from the number of cases observed. Our experience in this matter is as yet too small."

An article by Carl Rosenthal,[3] entitled "Ueber das Labferment nebst Bemerkungen über die Production freier Salysäure bei Phthisikern," was published in the *Berlin. Klin. Wochenschr.* of last December. In this paper Rosenthal examined the stomach contents of nine phthisical patients, and found an absence of hydrochloric acid in all, although some of the patients furnished no stomach complaints whatever, and had a good appetite. Rosenthal writes as follows: "It was shown that the stomach contents of patients with phthisis pulmonum, in the progressed as well as in the early state, contained no free hydrochloric acid." Rosenthal does not state whether he examined only these eight patients in reference to their stomach, and found hydrochloric acid absent in all, or whether he examined a larger number and failed to find hydrochloric acid in only eight. But, from his remarks above, it is evident that Rosenthal holds the opinion that phthisical patients have no free hydrochloric acid in their stomach. Taking into consideration the great importance this subject bears upon the dietetics of phthisical patients, I thought it necessary to investigate the condition of the stomach in these cases.

The material consisted of patients at the German Dispensary, and of two at the Montefiore Home for Chronic Invalids. The patients examined had clearly pronounced and easily detected phthisis pulmonum; some of them were already in the *stadium ultimum*. All examinations of the stomach were made one to one and a half hour after Ewald's Probefrühstück (trial breakfast), consisting of one cup of tea (without any sugar or milk), and a roll. The stomach contents were obtained by the expression-method, filtered, and examined. To test for hydrochloric acid we made use of only Günzburg's phloroglucin vanillin reaction, as being the best and surest test, according to my report of last year.[1] The degree of acidity was made out by the number of c.c. of a $\frac{1}{10}$ normal solution of sodium hydrate used to neutralize 100 c.c. of the filtered stomach contents, and written in this way.

The results of the investigation I subjoin in the table on next page:

We found it advantageous to range the patients in our table according to the degree of acidity. As the degree of acidity normally varies one hour after the Probefrühstück between 40 to 60, the following can be noted with regard to the above-mentioned table:

1. Among the 15 cases of phthisis pulmonum examined, free hydrochloric acid was absent only in two of them (14 and 15); in a third patient (11) the hydrochloric acid was wanting but once, and was present upon two other examinations; in all other patients the hydrochloric acid was always present. In this way our results differ from those of Rosenthal.

2. As regards the acidity, in 5 patients (6 to 10) it was found normal; 5 (1 to 5) showed hyperacidity; and 5 (11 to 15), a diminution in the degree of acidity; among the last group there were 2 with a total absence of free hydrochloric acid.

3. Only 1 patient (4) had in his stomach, after the trial breakfast, the remnants of the yellow of an egg, which he ate on the day previous, and that but once. In all other patients we found in the stomach contents no food whatever except the fine pieces of the roll. Their stomachs must have been empty before taking their breakfast. Therefore it can be concluded that the motile power of the stomach was not diminished in a very high degree.

4. In most cases a record of the appetite was kept. *A priori*, one would be inclined to think that the appetite is in a certain degree dependent upon the amount of gastric juice secreted. As the amount of gastric juice secreted is measured by the degree of acidity, the appetite ought to be good where hyperacidity, or a normal amount of acidity, exists, and bad where there is present a diminished degree of acidity. But this is not true, as can easily be seen from the above table. Three patients with hyperacidity (1, 3, and 4), and 2 with normal acidity (8 and 10), complained of poor appetite, whereas patient No. 15 had a good appetite, although there existed a state of complete absence of the free hydrochloric acid in his stomach.

In many of the patients we found, in the stomach contents obtained by means of the stomach-tube, sputa showing the same qualities as they appear when being ex-

pectorated by the patients; the sputa found in the stomach contents also presented the same bad and fetid odor. As regards the cause of dyspepsia in patients with phthisis, the views as yet are not settled. Cannot it be imagined that in many cases the cause of the dyspeptic conditions is to be looked for in the swallowed sputa? The sputa and the secretions from the nose and fauces, flowing down through the œsophagus into the stomach irritate the stomach walls and give rise to abnormal conditions.

As regards the therapeutics, it can easily be seen from the investigation that we must not give hydrochloric acid to phthisical patients for a deficient appetite; for in most cases there was no decrease in the amount of hydrochloric acid secreted by the stomach. On the other hand, we warmly advise the use of creosote in all cases of phthisis pulmonum. All the above-mentioned patients (with the exception of 8 and 15, belonging to the Montefiore Home) were treated with creosote, which I usually give in the following formula:

℞. Creosote 10.0
Tr. gent. comp 20.0
Dose: Twenty drops three times a day in a glassful of water.

In most of the patients taking creosote I could observe a certain decrease of the morbid symptoms; but more evident yet, there was nearly always an increase in appetite.

NOTE.—After completing this article there appeared in Germany at the same time two papers on "Dyspepsia in Phthisical Patients," one written by Klemperer,[1] and the other by Schetty.[2] The results obtained by these authors resemble very much my own. Notwithstanding this fact, I do not consider it necessary to omit the publication of the results of my investigations.

In the second part of my present article I desire to make a few remarks relative to the condition of the stomach, as regards hydrochloric-acid secretion in sea-sickness. In the literature of this subject there is found, as far as I know, but one remark, viz., that of Ewald;[3] the same is translated into English as follows: "Thus I found my own stomach contents, during a nicotine poisoning which lasted but a very short time, completely free from hydrochloric acid; another time, on a sea trip, when I had taken my breakfast on board, and was forced in about an hour to vomit, I could not find in the vomited contents, by means of Congo paper, any reaction."

On my trip from Germany hither, on the steamship Trave, I took up the opportunity of examining the condition of the stomach regarding hydrochloric acid during sea-sickness.

The material consisted in the vomited masses of myself and three other sea-sick people. The vomit was examined for hydrochloric acid by the phloroglucin-vanillin test, and was found as follows:

Table on the Relation of Hydrochloric Acid in the Vomit during Sea-sickness.

Name.	Date.	How long after meal vomited.	H Cl.
1. L. B.....	July 21, 1888.	½ an hour.	o
	July 22, 1888.	4 hours.	+
2. M. E.....	July 21, 1888.	20 minutes.	o
	July 21, 1888.	5 hours.	+
	July 22, 1888.	3 hours.	+
	July 23, 1888.	4 hours.	+
3. S. G.	July 22, 1888.	1 hour.	o
4. S. C.....	July 22, 1888.	4 hours.	+

As can easily be seen by the above table, hydrochloric acid was always present in the vomited contents, when vomiting ensued some hours (three to five hours) after partaking of a meal. This proves that the secretion of hydrochloric acid in the stomach during sea-sickness is not checked.

122 EAST FIFTY-NINTH STREET.

NAREGAMIA ALATA.—The air-dried stems and root of naregamia alata or Goanese ipecacuanha, have been the subject of further therapeutic trials by Surgeon-General Bidie, who reports that, on the whole, the results have been satisfactory and such as to encourage the further use of the drug. It is thought probable that in mild cases of dysentery the indigenous remedy may be of use in supplementing the true ipecacuanha. Specimens of the naregamia alata have therefore been planted with a view to testing its rate of growth in the botanical gardens in Nilghiris.—*The Medical Age.*

LONG INCUBATION OF SYPHILIS.—Dr. Falcone reports a case in which the incubation period of syphilis was nearly two months. A man was seized with an attack of typhoid fever, and took to his bed on July 22, 1886. The fever lasted six weeks. On September 15th he felt slight pain at the right side of the frænum. On September 24th induration was present and syphilis was diagnosed. The disease ran a regular course. The patient stated that the last sexual intercourse took place on July 21st, the day before he was attacked by typhoid. According to this the primary sore appeared on the fifty-sixth day after contagion.

FISTULA IN ANO IN THE FEMALE, OPERATED ON BY SUTURING.

By HUBBARD W. MITCHELL, M.D.,
NEW YORK.

In doing the operation for fistula in ano by suturing with silver wire, a departure has been made from the old method which has been in vogue from time immemorial. This old method consisted, briefly stated, in inserting the finger through the sphincter into the rectum, and passing a blunt-pointed bistoury up the fistulous tract until its end could be felt by the finger; then simultaneously withdrawing both finger and knife, laying open all the tissues by a clean sweep, into the bowel. This included skin, muscle, and sphincter ani. The wound thus made was stuffed with cotton, lint, or an oiled pledget, and left to heal by slowly granulating from the bottom. The patient was put in the knee-elbow position, or astride a chair, or on his back or side, according to the fancy of the surgeon, and many of the descriptions of this operation, in the old text-books, treated of it as a rather trivial affair.

Whenever the wound was left to heal by the slow process of granulation, it was tedious at the best, and weeks were often passed before the patient was about again.

Whenever a fistula in ano exists, whether it is the result of a rectal abscess or a point of ulceration in the rectal wall, it is usually chronic in its character when it comes to the attention of the surgeon. The fistulous tract is usually more or less contracted and indurated, and lined by a freely secreting pus-membrane. The pus may be bland in character, or it may be irritating and extremely offensive. Pain is rarely absent, and this is usually the symptom that leads the sufferer to seek relief. It is sometimes very severe, at other times slight, and is described as dull, or heavy, or aching.

A typical fistula in ano presents, upon examination, a small orifice seated somewhere near the verge of the anus, on one side, or above, or below. It may be close to the external edge of the sphincter ani muscle, or it may be two or even three inches from it. The skin surrounding it presents a contracted and corrugated appearance, and upon pressure exudes a drop of pus.

If a silver probe be inserted in this orifice it will pass upward and inward, and touch the finger inserted in the rectum. Of the varieties of fistulæ it is not necessary to speak, since they all demand about the same method of treatment.

When we are called upon to treat such a condition of things, a question of some gravity confronts us. To be sure, it must be freely laid open, but after it is laid open, what is the next step? If we can help the wound to heal by first intention, and save the patient from the slow process of granulation, we shall certainly accomplish a great deal. It was with this idea in view that a departure was made from the older mode of operating, and an attempt made to close the wound by sutures, just as we would attempt to close any other wound by sutures.

The results attending this effort to induce primary union, by suturing the wound in the operation for fistula in ano, will be seen in the narration of the following cases.

These cases were all in the female, and all of them were complicated by uterine lesions, upon which an operation was done at the same time as the operation on the anal fistula.

Case I.—On June 23, 1887, Mrs. K. G —— presented herself for treatment. She was a widow, thirty-five years of age; had been married eight years before, and six years ago she gave birth to her first child. Has not been pregnant since. Just before her marriage she had an abscess on the right side and a little above the anus. This broke, but has never healed. She has suffered dull pain ever since, and a constant discharge of pus, which has always been more copious while at stool. During the past year her general health has been impaired, and she is now decidedly anæmic. Upon examination she presented the following symptoms: On the right side of the anus and one and one-fourth inch from its verge, was a small, hard, dull-red looking spot, from which fetid pus oozed upon pressure. A probe inserted into the orifice passed upward and backward into the bowel, two inches above the sphincter muscle.

Pain in the back and continuous leucorrhœa led me to examine the uterus. A severe bilateral lacerated cervix uteri was found, with granular, thickened, everted edges, covered with pus, and intensely inflamed. The uterus was sharply anteverted, and pressed strongly upon the bladder.

She had not suspected uterine trouble, but had attributed all her sufferings to her fistula. On July 6th I did the following operation:

She was placed under the influence of ether, and the lacerated cervix closed in the usual manner by seven silver wire sutures. She was then changed from Sims position to her back, a grooved director was inserted in the orifice of the fistula, carried up into the bowel, and then brought out at the anus. Upon this all the tissues were completely cut through, leaving a large open wound. The fistulous tissue could be felt at the bottom of the wound, hard, smooth, and glistening. All this was freely and radically dissected out with the knife and scissors, until nothing remained but a clean, healthy wound. This was thoroughly cleansed, and then closed in the following manner: A strong curved needle, armed with No. 28 silver wire, was inserted one-half inch back from the edge of the wound in the healthy skin, and carried down deeply below the bottom of the wound, and then up and out at a corresponding point on the opposite side. The wire included the entire depth of the wound. Three such sutures were passed, the innermost one close to the edge of the sphincter ani muscle. The wires were then twisted, bringing the edges of the wound closely and evenly together.

Two intermediate silk sutures were used to keep the edges of the skin in continuity. Iodoform was dusted on, and the whole dressed with absorbent cotton, secured by a T-bandage. The bowels had previously been emptied by hot-water enemata, and were now kept quiet by small doses of tr. opii. The patient was now put to bed, and light liquid diet ordered, such as soup, milk, etc. On the seventh day, July 13th, the wires were removed, and the wound had healed so completely by first intention that it was difficult to locate the original site of the fistula. The bowels were moved for the first time by a hot-water enema, without pain.

Three days later, July 16th, the uterine wires were removed, the cervix having also healed by primary union.

The patient was discharged perfectly cured.

Case II.—August 10, 1887. Mrs. A. B——, aged thirty-four, married. Six years ago her first baby was born. She had a difficult labor, and the child was delivered by forceps. Since then she has had two pregnancies, both terminating in abortion, at three and four months respectively, without known cause. Soon after her first labor she had an abscess near the rectum, which broke itself, but which has never healed. It would swell occasionally, and then discharge freely, but has never been free from discharge. For the past eighteen months she has been an invalid, unable to attend to any but the lightest duty. She has had pains in the back, bearing down pains, and persistent leucorrhœa. She is anæmic, has insomnia, and constipation. Examination revealed a severe bilateral lacerated cervix, with the stereotyped condition of metritis, thick, everted lips, and muco-purulent discharge.

On the left side, one and three-quarters inch from the anus, was the hard, contracted orifice of a fistula. A probe inserted into this passed directly into the bowel, about one and one-half inch above the sphincter muscle.

August 12th. Patient was etherized, and the cervix closed as in Case I., by seven silver wire sutures. The fistula was laid freely open on a grooved director, all pyogenic tissue thoroughly and radically cut away, and the

wound evenly and firmly closed by four silver wires, passed deeply below the bottom of the wound, as in Case I. Two silk sutures were passed superficially in the edges of the skin. Wound dressed by iodoform and absorbent cotton, and patient put to bed. Light diet. Bowels kept quiet by tr. opii.

August 19th, the wires were removed, and the wound had healed perfectly by first intention.

Three days after, August 22d, uterine wires were removed; wound healed completely. Bowels moved on the eighth day by hot-water injection. Slight pain. Patient discharged cured.

Case III.—September 3, 1887. Mrs. S. S——, aged twenty six, married. Had one child two years before, none since. Patient is very obese. Has been treated by a homœopath for what he called a patch of eczema near the anus. She can give no history of it, except that she has had it for more than two years. It has discharged almost continually, and has been always very painful. She applied to me for a chafing near the perineum, where the fleshy nates come in contact. She suffered from leucorrhœa, and complained of pain during coition, but was positive she had no uterine trouble.

Examination revealed a severe unilateral lacerated cervix, granular, thickened, and inflamed. A fistulous opening was seen on her right side a little above the level of the anus, and one and one-half inch from it. A probe inserted into this passed directly into the bowel, nearly two inches above the sphincter. Besides this, she had a very large external hemorrhoid running a little way up the raphe.

September 7th, patient was placed under ether, and the cervix closed, as usual, by five silver wires. The fistula was laid open on a grooved director, all unhealthy tissue freely dissected out, and a clean wound made.

The hemorrhoid was ligated and cut off. The large fistula-wound was then closed in the same way as the others, by four silver-wire sutures and three silk sutures, dressed as the others, and the patient put to bed.

Seven days later, September 14th, the wires were removed, and so completely had the wound healed that not a trace of the fistula remained, nor anything to mark where it had been.

September 17th, the uterine wires were removed, and union had taken place here also by first intention. The patient was dismissed well.

Case IV.—December 9th. Mrs. C. M——, aged forty, married, mother of eight children, came to consult me about some difficulty in micturition. During the past year she had had some trouble in passing water, and at times it had dribbled from her, so as to annoy her by chafing. This is all she complained of.

An examination revealed a terrific state of things. Her perineum was lacerated down to the fibres of the sphincter ani muscle. She had a rectocele as large as a good-sized orange; a cystocele about as large as a hen's egg. This was what gave her the urinary trouble she consulted me about. She had a severely bilateral lacerated cervix uteri, which was thickened, granular, and so widely everted that it looked like a horse's mouth. The uterus was beginning to prolapse. Besides all this, she had an ugly looking fistula on the right side, fully two inches from the verge of the anus, and opening into the bowel one inch above the sphincter. From this oozed a thin, sanious, offensive pus. Her general health was greatly impaired, but the duties of a large family compelled her to keep about her house.

December 12th, she submitted to the following operation: Under ether, the cervix uteri was closed in the usual way, by ten silver-wire sutures. The perineal walls or sides were extensively denuded, and six silver wires were passed deeply from one side across to the other, and properly twisted. This closed her perineum, and almost abolished her rectocele and cystocele. A grooved director was then inserted into the orifice of the fistula, and carried up into the bowel and out at the anus. The parts were cut through, and all the fistulous tissue was most radically dissected out, down to perfectly clean, healthy tissue. Several small vessels were tied, as the part was unusually vascular. The wound, which was very large, was closed by five silver wires, deeply passed, as in the other cases, and securely twisted. Wound dressed, and patient put to bed. For three days her urine was drawn with a catheter. Bowels kept quiet by tr. opii, as needed.

Seven days later, December 19th, removed wires from perineum and fistula. Both had healed solidly and perfectly by primary union. Three days after removed cervical wires. Wound completely healed, patient entirely cured.

Case V.—This case was unique, and deserves a place by itself in the archives of gynecology.

The patient, Mrs. C. G——, aged twenty-six, married, came to me on February 28, 1888, for treatment. She was petite in stature, and lamb-like in demeanor. Her four and a half years of marital felicity had been fruitless.

She complained of great nervousness, and pain on coitus.

Examination revealed a fibroid tumor in the cervix uteri, spheroidal in shape, and 1½ inch in its longest diameter by 1¼ inch wide. Its pedicle was attached to the left wall of the uterus, about half an inch above the inner os. The cervix was highly inflamed, patulous, and foul and sloughy.

On the left side of the anus there were three fistulous openings. These formed a triangle, and were two inches from the anal verge. A probe, passed in, showed that two of these fistulous tracts opened by one aperture one inch above the sphincter in the bowel, and the other opened by a separate aperture two inches up the bowel.

Besides all this, there was an obstruction of the rectum 2½ inches from the anus, which proved to be a firm, fibrous diaphragm, or circular shelf, as hard and unyielding as cartilage. It was perforated in the centre by a round opening ⅛ inch in diameter. It could not be dilated in the least. Such an obstruction suggested cancer or syphilis, but a rigid inquiry failed to discover the history of either. It was decided to remove the uterine fibroid at once, which I did by grasping the pedicle with a slender forceps, and carefully twisting it off. This left the cervix uteri widely dilated, like the mouth of a trumpet.

The patient's general health was cared for, and on April 8, 1888, I did the following operation:

Under ether the cervix, which was still widely dilated, was treated like a laceration and closed by seven silver-wire sutures. The three fistulæ were divided on a grooved director, and as the tissue forming the triangle at the openings was infiltrated and diseased, it was completely cut away until a healthy wound was made. This was sufficiently large and deep to admit a hen's egg.

The wound in the bowel was enlarged up to the obstruction. This was cut through its entire thickness on one side. Several twigs of the inferior hemorrhoidal artery were divided and ligated.

The large fistula-wound was then cleansed, and closed with four silver-wire sutures, and one tension suture passed deeply, and held by lead buttons; three superficial silk sutures approximated the edges of the skin, and the whole was carefully dressed with absorbent cotton.

She suffered little or no pain, but her conduct every night for the next four weeks was something to be remembered. She kept quiet during the day, and entertained a host of friends, in spite of all remonstrances; but at night she would roll about the bed, tear off her dressings, kick violently at anybody who went near her, and scream horribly.

A demijohn of sherry and a goblet, and a large basket of assorted fruit, always stood near her bed, of which she partook ravenously. Primary union, or any union of the wound, was impossible under the circumstances. In two days the wound sloughed, and as the wires were bare and were tearing the skin, they were removed. Her bowels, under the influence of the fruit and wine, and her noc-

turnal tirades, moved involuntarily and frequently, with a copious diarrhœa, which, in spite of the nurse's efforts, kept the bed and her person in a constantly soiled condition. She passed her urine in bed; she would take no opiates; she was uncontrollable and fiendish.

This condition of things lasted four weeks, and the wound showed no signs of healing. One day, in a penitent moment (the first she had had), she confessed to a clandestine meeting two years before with an old lover, who left her with a chancre on her vulva. This was followed by a general cutaneous eruption, sore throat, loss of eyebrows, and pains in her bones.

From a fear that her syphilis would return, she was induced to behave, and I gave her potass. iodide, gr. x., three times daily, with a little morphine at night. Under this treatment she began to improve, and by June 1st the wound had healed by granulation. The bowel obstruction slowly became absorbed, and ultimately disappeared.

It will be noticed that in each of the above cases of fistula in ano there was a complication of uterine disease, for which an operation was done in addition to the operation for the fistula. Yet in the first four cases the result was perfect. It is fair to suppose from this that in a case of fistula in ano, without other disease, the operation by suturing would be, in a large percentage of cases, successful; sufficiently so, at least, to satisfy us in attempting it, and saving our patients from the slow and tedious process of healing by granulation.

These cases were not selected. They came in the ordinary course of practice. They were all severe cases, with severe complications, yet four out of five healed by primary union.

Perhaps four cases are not enough to judge correctly of the value of any operation, but they are recorded simply as a contribution to this interesting and important subject.

The fifth case should not, perhaps, have been classed with the other four. The failure was not due to any lack of care in the operation, nor in the after-treatment, but was one of those cases, met with by almost every surgeon, where the patient was absolutely beyond control.

The history of syphilis was concealed before the operation. But the close stricture of the rectum made some interference imperative, and under the circumstances its complete division was the only thing to do, otherwise occlusion of the bowel would have ensued in a very short time. If cases of fistula in ano in the female can be induced to heal by first intention, especially when they are handicapped by uterine complications, it seems to me that simple fistulæ can be made to heal quite as readily by the operation of suturing.

The method of passing the sutures is important. If the suture is entered on one side, and simply passed through the skin and subjacent tissues, and then out at the other, I should expect the operation would fail, although I have never done it in this way. But in the five cases above narrated I entered the suture well back in the skin from the edge of the wound, and carried it below the bottom of the wound, and up and out at a corresponding point on the opposite side. In this way the whole depth of the wound was held firmly together, so that the sides could not move on each other, and thus prevent union. The superficial edges of the skin were held, as above stated, by silk sutures. All the fistulous track itself was radically dissected out, which left a clean, healthy wound. This seemed important, for primary union could not be expected if the firm, hard, glistening, and diseased tissue surrounding the fistula were left in the wound.

If a fistula in ano, either in the male or female, were converted into a healthy wound, closed by proper suturing, and the patient treated as any surgical patient, with a due regard to rigid cleanliness, rest, and diet, it seems reasonable to expect a union by first intention here as anywhere else.

I believe it is important to have the bowels completely emptied before the operation, by copious hot-water injections, and to keep them locked up by sufficient doses of tr. opii until the wires are removed. A disturbance of the wound by an alvine dejection would certainly interfere with primary healing. If perfect quiet of the parts is maintained by an empty bowel, opium as needed, rest, and a light diet, we have done all that it is possible to do to insure for our patients a speedy recovery.

747 Madison Avenue, March 28, 1889.

Clinical Department.

A UNIQUE NON-CAPSULATED FATTY TUMOR OF THE NECK—REMOVAL, WITH LIGATION OF ALL THE JUGULAR VEINS EXCEPT THE LEFT INTERNAL—RECOVERY.

By PAYSON T. HUCKINS, M.D.,

Los Angeles, Cal.

Mr. H——, aged thirty-five, laborer, of good general health, consulted Dr. K. D. Wise, of this city, in the spring of 1884, for an enlargement encircling the whole circumference of the neck, extending anteriorly from the inferior maxillary bone to the sternum and clavicles, posteriorly from the occipital protuberance and around the occipital bone as far as the seventh cervical vertebra, and to the superior angle of the scapulæ.

The history of the patient evolved the fact that six years previous he had noticed a small soft lump under the body of the inferior maxillary on either side, within a short distance of the symphysis, and that these lumps had gradually extended and involved the whole neck. This enlargement was seriously interfering not only with the patient's looks but his comfort, the circumference of the neck being much greater than that of the head. The neck measured before the operation twenty-five inches, and after the removal of the tumor thirteen and one-half inches. The circulation was greatly impeded in the capillaries of the skin over the tumor and face, giving the patient the appearance of a brandy drinker. His comfort was greatly impaired by the pressure of the fatty mass interfering not only with the circulation but with deglutition, and under active exercise with respiration.

There was no strumous or syphilitic history.

Dr. Wise, after consulting with Dr. Huckins, decided to remove the tumor, and after a few weeks of preliminary treatment the patient was etherized by Dr. R. C. Kirkpatrick, and Dr. Wise, assisted by Dr. W. W. Ross and Dr. Huckins, began the operation by making a curvilinear incision on the left side, extending from a line two and one-half inches below the mastoid process of the temporal bone to about the same distance below the symphysis of the maxillary bone, dividing the sterno-cleido-mastoid muscle; but, finding the tumor was not capsulated, a crucial incision was made from the angle of the inferior maxillary to the sterno-clavicular articulation. The process of dissection was then begun, and after two hours of tedious work, severing attachments from all the deep-seated vessels, nerves, muscles, and aponeuroses, ligating blood-vessels, checking hemorrhage by hot water and pressure, one-fourth of the tumor was removed piecemeal. The operation was thoroughly antiseptic, the incisions being united by carbolized silk sutures, drainage-tubes inserted, and the patient kept in bed for two weeks. The incisions united by first intention.

The second operation, performed six weeks after the first, consisted in making a straight incision from two inches back of the mastoid process downward to the clavicle, and from the beginning of this incision backward to the nucha. After about two hours of wearisome dissection, removing a piece not larger than a walnut at any one time, this portion of the neck was dressed as in the preceding. The greatest difficulty in this part of the operation was to sever the deep fibrous attachments, some of which extended to the transverse and spinous processes of the cervical vertebræ. The patient made a rapid recovery

from this operation, the wound healing kindly, and in four weeks he was again anæsthetized, and the operation was begun on the right antero-lateral side. The incisions were made as in the first operation, all went well until this mass was about half removed, when the internal jugular vein was injured just below the point of bifurcation of the common carotid artery, and a full expiration sent a gush of blood over the patient. Dr. Wise instantly grasped the vein between the thumb and forefinger of the right hand, and thus prevented an undue loss of blood and the entrance of air into the vein. Rapid cyanosis followed, and for a time it seemed as though the patient would not rally; but proper treatment soon restored the circulation, and Dr. Huckins enlarging the rent in the common sheath of the vein, artery, and nerve, and isolating the vein, applied a carbolized catgut ligature to both proximal and distal ends. The operation was finished in about three hours. The patient, being very tractable, was kept absolutely quiet, and had nothing to eat or drink for seven days except a tablespoonful of equal parts of milk and water every hour. He made a rapid recovery, not having an untoward symptom. At the end of two months the remaining fourth of the tumor was removed in the same manner as in the second operation.

About five years have elapsed, and the patient is now in perfect health. He has never complained of any fulness in the head, or any headache, and there is no evidence of any recurrence of the growth. I would emphasize the fact that all of the jugular veins were ligated except the internal on the left side, and still the patient suffered from no impediment to the circulation, which I think was in a measure due to the almost starvation diet, as well as to the necessary division of the operation into four periods, which gave ample time for the establishment of the collateral circulation.

Lipomatous or fatty tumors usually have a distinct fibrous covering or capsule which is supposed to be derived from the connective tissue of the parts occupied by the growth, and in a measure depends upon the amount of loose connective tissue in the region of the growth. There are also distinct fibrous prolongations dipping into the fatty mass and separating it into lobes, lobules, and granules, and forming attachments to the vessels, muscles, fascia, and bony prominences.

The tumor in question had no connective tissue or capsule surrounding it, and yet it had all the microscopical appearances and other characteristics of a fatty growth, and not that of normal adipose tissue; but there were fibrous bands dividing and subdividing the mass, and forming firm attachments to the vessels, muscles, and bony processes. It would not have been unusual to find a very attenuated capsule or no capsule in the back of the neck, for there is very little connective tissue there; but in this case there was no capsule over any part of the tumor, and furthermore, there was no connective tissue, the lipomatous tissue adhering closely to the skin and muscles, and had to be peeled off with the fingers and handle of the scalpel. When the skin was laid over the seat of the operation and sutured, there was great fear of sloughing.

I would state that the skin after the operation adhered to the muscles and vessels, but has become loose since, probably by the formation of normal cellular tissue. I will also state that the diagnosis of lipoma was made before the operation.

A LAPARO-MYOMOTOMY.

By DEWITT G. WILCOX, M.D.,

BUFFALO, N. Y.

It is Dr. Abbe who suggests that it should be a surgical axiom that every case of operative interference should be published. Acting upon that suggestion I present the following merely as a contribution to a subject of which we read much, but which as yet is not made perfect.

The patient, being an intelligent, observing woman above the average, was able to give me a very comprehensive history of her sufferings, which I append very nearly in her own words. It is interesting as showing the behavior of fibroid tumors under varying circumstances: "About six years ago," says the patient, Mrs. K——, who is fifty years of age, "I took two Fresh Air Children from New York to enable them to enjoy a respite from that heated city, and obtain the fresh air of the country. I rocked and lifted them more than I realized. The next day I felt sore across my abdomen, and putting my hand there felt a hard tender ridge extending upward nearly to the navel. After six weeks, during which time it did not abate, I sent for my physician, Dr. Truman, of Belmont, who then diagnosed a uterine fibroid. It seemed to be club-shaped, and the upper end was free and easily movable. He prescribed local and constitutional treatment, which was followed for two years, with an abatement of all acute symptoms. Then I had an attack of gastritis and could retain no food for eight days. At this period I was examined by another physician, and my bowels being emptied, he had a better opportunity of making an examination. He found the same club-shaped tumor freely movable under the skin. Soon after I had much backache, and could be upon my feet but a few hours at a time, had also a constant bearing-down pain with nausea. A year later I had a second attack of dysentery, which reduced me greatly. The backache and bearing-down increased, and in addition there was a fulness and tenderness in the vagina not before noticed. I had had great difficulty for years in obtaining a passage from the bowels without an enema. In October, 1888, the distress became so severe that I would frequently faint during an evacuation. In December last another examination was made, when the tumor, which heretofore was easily felt beneath the abdominal walls, could not be found, nor any trace of it. I had not had an examination made previous to that for some time, and had not noticed its disappearance." This is in substance her history.

When I examined her, January 28, 1889, I found, per vaginam, a hard, resisting body in the posterior cul-de-sac, filling up the hollow of the sacrum and firmly adherent. I could not lift it at all from its position; the rectum seemed almost if not quite occluded. The cervix and os were normal, nothing definite could be obtained by bimanual examination. I diagnosed a subperitoneal uterine fibroid on the posterior surface of the uterus causing a retroflexion of that organ and thereby allowing both the tumor and the fundus uteri to fall into the hollow of the sacrum. The diagnosis was quite in accord with that afterward given me by the family physician, Dr. Truman. The dangers were complete occlusion of the rectum, which was gradually taking place, exhaustion from pain, and lack of assimilation. At her urgent request the operation was undertaken, the bowels were as thoroughly emptied as possible, and the belly was shaved and scrubbed. An incision was made in the median line, and the hand being inserted, a retroverted fundus was felt, and the fibroid back of it, beneath the peritoneum, firmly bound down to the rectum. There was also on the fundus a small pedunculated fibroid, about the size of a walnut, and hysterectomy was impracticable from the firm attachment of the uterus to the rectum through the tumor, also from contractions of the broad ligaments rendering it almost immovable. Enucleation was decided upon. First, the small pedunculated fibroid was removed by transfixing the pedicle and firmly ligating it, cutting off the tumor and then stitching the peritoneum over the stump. An incision was then made anteroposteriorly, extending from the fundus uteri back to the rectum, just through the peritoneum. Two fingers being inserted between this membrane and the fibroid, this separation was carried on until the tumor could be raised above the fundus; it was found to be "double-headed," a constriction in the middle making it appear bifid. Some of its attachments to the uterus were torn off in separating the peritoneum, so that the remaining pedicle

was not much larger than a child's wrist. As soon as it could be raised from its bed the pedicle was transfixed and firmly ligated with braided silk wound three times around, then the pedicle was ligated *en masse*. the fibroid cut off, and the stump stitched over with peritoneum. After washing out the cavity there was observed to be some hemorrhage. Seizing the fundus with the volsellum and bringing it forward, and passing a small incandescent electric light into the cavity, it was found that the oozing came from the posterior surface of the fundus, and not at all from the stump. There was an area of about one square inch that bled quite freely. The abdominal cavity was freely flooded with hot water in the hopes to check it, but was of no avail. Clamp forceps could not catch the bleeding points, as they were too general—not at all defined. Again the fundus was raised up by the volsellum, the light introduced, and the peritoneum brought from the two sides and stitched over the bleeding surface This seemed to check the hemorrhage. The cavity was again washed out, a glass drainage-tube was inserted in the lower angle of the wound, and the peritoneum and the fascia were sewed separately. Twenty-four hours afterward the dressings, which were saturated with blood, were changed. At the end of thirty-six hours the tube was removed. It was found filled with a partially organized clot, which came away with the tube. Iodoform gauze was then inserted as drainage, and the patient made a good recovery, from that time on having no elevation of temperature and but little nausea. The dressing was not changed again for five days, except the drainage, which was continued two days longer. The incision healed by first intention, and the drainage opening granulated soon after. The patient had movements of the bowels at the end of four days, and has had easy movements since, has no backache and is able to walk comfortably.

Progress of Medical Science.

THE ETIOLOGY OF RHEUMATIC FEVER.—Dr. Pel, of Amsterdam, has written instructively on this subject. Although no specific germ of infection has as yet been found (*British Medical Journal*), there is reason to suspect the existence of such a germ, and for looking upon acute rheumatism as an infectious disease. For example, it is liable to occur in epidemics, which not uncommonly bear distinctive characters. The disease commences with a disturbance of the general health, accompanied by fever, the joint affections only declaring themselves subsequently; and it is frequently complicated by inflammations of the endocardium, pericardium, and other serous membranes, which of itself is presumptive of the infectious character of the disease; but confirmatory evidence of the discovery of a specific micro-organism in the inflamed membranes is still required. Much of the more recent literature of the subject points decidedly toward the disease having a specific origin. In the Amsterdam Hospital it is found that rheumatic fever often attacks patients in batches, and "rheumatism days" are spoken of, when this occurs in a marked degree. During April, May, and June, 1884, the cases were mild as regards the joint affection, but nine of them were complicated by affections of the serous membranes. All, however, were convalescent in three weeks. In August and September, 1884, the cases were slight, but there were repeated relapses of the joint affection, also anæmia and functional cardiac murmurs. In February and March, 1884, the cases were complicated by pleurisy, pericarditis, endocarditis, etc.

In August, 1885, an instructive case occurred of a female patient, aged forty-three, who, after recovering from enteric fever, followed by double pneumonia, while able to walk about was suddenly seized with symptoms of acute rheumatism, and passed through a somewhat sharp attack. She had never had any rheumatic symptoms previously, and while in hospital was removed from damp, etc. She, however, occupied a bed between two other patients with rheumatic fever, and her attack coincided in point of time with a relapse in five other rheumatic-fever patients. Other cases pointing to direct infection are quoted from Salisbury, Pocock, Schäfer, and Thoresen. Professor Pel then proceeds to discuss the relationship of rheumatic fever to climatic conditions and to malaria. He is inclined to agree with Bertholon in regard to there being a distinct connection between malaria and rheumatism, the years when malaria is prevalent in Amsterdam being remarkably free from rheumatism. The papers of Gabbet and Edlefsen, on the relation of acute rheumatism to temperature and rainfall, are quoted by the author, who states that on comparing the hospital registers with official meteorological tables, it was found that the so-called rheumatism days did not occur during a lengthened period of excessively rainy weather, that the actual temperature had apparently less influence than the extent of the diurnal variation, also that some five to ten days previously to a "rheumatism day" a great quantity of rain had generally fallen. There is evidently, therefore, some connection between the amount of rainfall and rheumatism, and the author's observations point apparently to the development of the specific *materies morbi*, whatever it may be, in the earth by moisture and its subsequent dissemination during dry weather.

β-NAPHTHOL IN TYPHOID FEVER.—Dr. J. M. Clarke states that β-naphthol is a substance very insoluble and having at the same time sustained and powerful antiseptic properties. Moreover, it is only toxic in large doses—about 250 grammes in the twenty-four hours for an adult of average weight—while forty grains, or 2½ grammes, distributed over the twenty-four hours are sufficient to keep the intestinal contents aseptic. But while giving naphthol it is also advisable to control the pyrexia that necessarily occurs in the course of enteric fever, and so to prevent the damaging effects on the tissues and organs of the body of a long-continued high temperature; we should therefore, together with naphthol, administer an antipyretic, preferably, perhaps, antifebrin or phenacetin, whenever the temperature rises beyond a certain height, say 102° F. With regard to the best form of administering naphthol, it was given suspended in milk, and a small quanity of pure milk was taken after the dose. The doses must be administered frequently, in order to keep a constant effect, and small doses have also the advantage of not giving rise to the pungent after taste in the throat that naphthol is apt to produce. To adults it may be administered in gelatine capsules, or the following formula, which seems the most satisfactory after several trials, may be made use of; ℞. β-naphthol, gr. xx.; tr. aurantii, ʒ ij.; syr. limonis, ʒ ss.; mucilaginis tragacanthi, ʒ iij.; aq., ad ʒ vj. Dose, ʒ j. Dr. Clarke formulates these conclusions: 1. The production of intestinal antisepsis is a rational mode of treatment of enteric fever, and that β-naphthol is a safe and tolerably efficient agent for this end. 2. By its use (in his cases) the duration of the disease was shortened, and the intensity of the symptoms directly arising from profound disturbance in the alimentary canal was lessened. 3. The tendency to the occurrence of splenic enlargement, albuminuria, and of secondary complications such as boils, abscesses, etc., of purlent infective origin, is diminished. 4. Complete convalescence is more speedily and satisfactorily attained: and there is less risk of a propagation of the disease to others. Finally, we must bear in mind that in some patients naphthol may excite so much gastric disturbance as to prevent its use.—*The Practitioner.*

THE ELASTIC LIGATURE AS A SUBSTITUTE FOR VENESECTION.—Dr. Walford writes, in the *British Medical Journal*, that he has used the elastic ligature applied to the limbs, as a substitute for venesection in pulmonary congestion, hæmoptysis, carditis, etc., for over twenty years, and values it highly.

AN ALLEGED HÆMATOZOON OF RELAPSING FEVER.

IN a communication presented at a meeting of the Medical Society of the Caucasus, in Tiflis (*Protokol Zasyedania* of December 16, 1888), Dr. N. A. Sakharoff described a parasite, found by him in the blood of patients suffering from relapsing fever, which resembles in many respects the hæmatozoon malariæ. The subjects of his study were six patients, received into the railway hospital in Tiflis from different parts of the Caucasus. In none of them could any history of contagion be obtained, but the diagnosis of relapsing fever was made from the presence in the blood during the stage of fever of Obermeier's spirochætæ.

On examining the blood of these patients soon after the beginning of defervescence, the author found numerous protoplasmic bodies of a dull whitish color and faint outline, varying in size, but usually much larger than the hæmatozoon malariæ; some being even as much as twenty times the size of a red blood-corpuscle. In several of these were found nuclei of a light gray color, and about the size of a red blood-corpuscle. In addition to the nucleus, each organism contained numbers of granules, some dark and some of a bright red color. Some of these granules were at rest, while others presented a rapid to-and-fro movement. On watching these bodies they were seen to possess amœboid properties, sending out prolongations of protoplasm from one or the other side. Sometimes these arms would be drawn back into the body of the corpuscle, at other times they would become constricted at one point and separate from the parent mass. In this way, at times, the entire mass of protoplasm becomes divided up, and the newly formed corpuscles separate from each other, leaving only the nucleus and the pigment granules, which then float free in the blood. The nucleus resembles a red blood-corpuscle; but whether it is one or not, the author is not prepared to say, although the fact that it is not visible in stained preparations leads him to think that it may be of such a nature.

In addition to these large masses there are other small amœboid bodies which Dr. Sakharoff describes as entering the red blood-corpuscles and giving rise to appearances similar to those seen in the blood of malarial subjects. These may be seen in great numbers in blood drawn directly from the spleen in the stage of apyrexia. These bodies increase in size at the expense of the blood-corpuscles, become filled with pigment granules, and finally assume the form and appearance of the large masses first described.

The origin of the spirochæte of Obermeier is also described by Dr. Sakharoff. In the blood may be seen a number of grayish bodies, possibly the nuclei above mentioned, which have been freed by the disappearance of the surrounding protoplasm, or possibly independent protoplasmic bodies, from which rays project at different points, giving them a star-like appearance. The author isolated one of these bodies in some blood taken from a patient eight hours before the occurrence of a fresh febrile paroxysm, and watched it for the space of about ten hours. It had three short rays or flagella projecting from its surface, and these had a very rapid oscillating movement. In the course of an hour these rays were seen to increase in length, one being considerably larger than the others. This one continued to grow at the expense of one of the others, which became smaller and smaller until it was finally entirely withdrawn. There were now but two rays, one larger than the other, inclined to each other at an obtuse angle. This angle finally disappeared, and in the course of ten hours the body had became transformed into a long thread, thicker than a normal spirochæte, and having a slow, wave-like motion. The author believes that he witnessed here the formation of the so-called spirochæte of Obermeier, attributing the greater thickness of the thread and its sluggish movement to the circumstances under which it was developed outside of the body and at the ordinary temperature of the room.

Dr. Sakharoff notes particularly the resemblance of this parasite to that found in malarial fever, and thinks that the points of similarity in the clinical picture of the two affections are thereby explained. Those are the protoplasmic bodies within the red blood-corpuscles, which, after a time, are seen to contain pigment granules. There are also the large bodies containing pigment granules. These are, however, much longer than the similar bodies seen in malarial blood, and are also endowed with amœboid movements, which the latter do not possess, and have possibly, though not certainly, a nucleus. Then segmentation of those large masses takes place. The rayed bodies from which the spirochætæ are developed are possibly similar to the flagellated bodies observed in malarial blood, and the spirochætæ may be the analogue of the free flagella.

Had not Laveran's discovery been shown, over and over again, by the most competent observers, to be true, these observations of Sakharoff would be in the highest degree improbable, and would scarcely seem worthy even of passing mention. As it is, they need the confirmation of other authorities before they can hope to gain evidence. It is not impossible that the author may have erred in his diagnosis, and that his patients were suffering simply from malarial infection, although he claims to have found Obermeier's spirochætæ during the febrile paroxysm in every case. On the other hand, it should be remembered that other observers have seen appearances similar to those described by Sakharoff, in cases of relapsing fever. Heidenreich found protoplasmic bodies resembling white blood-corpuscles, but larger, some of which were apparently nucleated, some homogeneous. Those containing granules he took to be fatty degenerated white corpuscles, although the addition of fat dissolving substances failed

From Dr. P. A. Morrow's Atlas of Venereal and Skin Diseases.

WILLIAM WOOD & COMPANY, Publishers, NEW YORK

to remove the granules. Gutmann saw numerous minute scintillating bodies, similar to those supposed by Sakharoff to be pigment granules, which he thought were the spores of the spirochætæ. Albrecht possibly saw the bodies from which the author believes the spirochætæ are developed; but, as he was searching for spores, seems to have attached but little importance to what he actually did see.

The following are the conclusions which Dr. Sakharoff formulates as a result of his investigations:

1. In every stage of relapsing fever there exists in the blood a hæmatozoon, in one or the other phase of its development.

2. Relapsing fever may be diagnosticated even in the apyretic period (most readily by the aid of stained preparations).

3. Judging from the morphological resemblance between the parasites of malaria and of relapsing fever, we may conclude that the latter, like malaria, may also arise from the soil (miasmatic), an assumption which is strengthened by the author's observations of sporadic cases of relapsing fever.

4. By the resemblance of the parasites to each other is explained also the resemblance of the symptoms of the two diseases, in consequence of which the affections have been, and still are, occasionally mistaken the one for the other.

5. The spirochætæ of relapsing fever ought to be excluded from the family of spirochætæ (schizomycetes) and be called pseudo-spirilla.

THE QUESTION OF CONTAGION IN CANCER.

NOTWITHSTANDING the very unsatisfactory nature of the evidence which has been brought forward in support of the contagiousness of cancer there are not a few who hold to this view. Several have claimed to have discovered a pathogenic micro-organism of the disease but none of these discoverers has had the satisfaction of finding his results confirmed by other investigators. Inoculation experiments upon animals with cancer-juice and with cultures of the micro-organisms have also failed to give results which can in any sense be regarded as conclusive. Inoculation upon the human subject has been tried in two instances at least, and has apparently succeeded. The first case was that of Alibert who derided the theory of contagion, and to show his belief in its falsity he inocu lated himself with cancer-juice, and subsequently died of carcinoma. The second case was one reported by Hahn, who inoculated the healthy breast with cancerous material taken from a tumor of the other breast. At the woman's death a cancerous growth was found at the site of inoculation.

In *La Normandie Médicale*, of February 1, 1889, Dr. Arnaudet relates his experience with cancer in the hamlet of Saint-Sylvestre-de-Cormeilles, which he regards as conclusive proof of the contagious nature of the disease. In this place, out of a population of not quite four hundred souls, there were seventy-four deaths in a period of eight years, and of these eleven were from cancer. This is certainly a large number, and, in proportion to the population, is over three times greater than the mortality from the disease in Paris. In the neighboring villages of Normandy, although exact figures are wanting, the death-rate from carcinoma is said to be nearly the same. Of these eleven cases six occurred within a limited area and the order of their occurrence was such as to suggest a possible connection between them. The first case was that of a man living in an elevated portion of the hamlet, the next case was a man living on the side of the hill below the first, then three cases occurred almost simultaneously in persons living close together in the valley at the foot of this hill, and the sixth patient was a near neighbor of the first on the plateau above the valley. In none of these cases could any history of heredity be obtained, and they were all free from the reproach of alcoholic addiction. In five of the cases the cancer was seated in the stomach, and in the sixth the location of the disease was in the neck.

Dr. Arnaudet believed that the germ of the disease, microbial in its nature, was carried in the water. None of the patients drank water, but they were all moderate consumers of cider and that was the beverage that the author accused of being the carrier of the contagion. In making cider the inhabitants of that region added water taken from the swampy ground, and the darker the color of the water, consequently the more impure, the higher it was esteemed as a diluent of the apple-juice.

Dr. Arnaudet's cases are hardly as conclusive as he seems to regard them, but they may serve as a contribution to the subject, and we give them for what they are worth, leaving to the contagionists the satisfaction of using them in support of their views, if they see fit to do so.

THE QUESTION OF FEBRILE ALBUMINURIA IN CHILDHOOD.

FEVER is frequently accompanied by the appearance of albumin in the urine. The precise mode of origin of pyrexial albuminuria, which, it must be remembered, is not an invariable symptom, has not yet been satisfactorily established. Nor can it be said that its prognostic significance is at all clear, some observers denying its importance altogether, while others have sought to claim for it a more or less serious meaning.

Some phases of this subject have been recently studied by Ekkert, and in the *Archives of Pediatrics* a *résumé* of the results of his observations has appeared. The author has endeavored to throw further light on the question of the relationship of different diseases to changes observable in the urine of children. And he has further tried to determine, at least approximately, the loss of albumin to the organism in connection with the albuminuria of fever. The material included one hundred hospital cases, of which thirty-one were cases of acute infectious disease, seven being cases of petechial typhus, nineteen of typhoid, two of recurrent, and two of intermittent fever. The urine was examined as to its daily quantity, color, specific gravity, the quantity of its phosphates and its albumin, if any. The albuminuria continued two or three weeks in one case of petechial typhus and in three cases of typhoid; from one to one and one-half weeks in four cases of petechial typhus and three of typhoid; during several days albumin was found in six cases of typhoid, and during one day in two cases of typhoid.

The author believes that he is justified in making the following statements:

1. Albuminuria in typhus and typhoid fevers is a very common phenomenon, occurring in three-fourths of all children who have these diseases.

2. Albuminuria occurs most commonly during the first week, or even during the first days of the disease.

3. It is difficult to define the normal duration of albuminuria; it probably averages one to one and one-half week.

4. The frequency of albuminuria in typhus and typhoid, and the quantity of albumin discharged bear close relation to the intensity of the febrile condition and the duration of the period and fever.

A certain number of cases of acute exanthematous diseases were also studied with reference to the relation of albuminuria to them, these being diseases in which the kidneys are most likely to be implicated, especially when they occur among children. Of the group of cases studied two were measles, two of diphtheria, and fourteen of scarlet fever, with secondary parenchymatous nephritis in different stages of development. The conclusion concerning these diseases was that the occurrence of acute eruptions is usually attended by febrile albuminuria, the intensity and duration of which depend entirely upon the intensity and duration of the accompanying fever. The albuminuria is generally of brief duration, and has no particular prognostic significance. In the third or fourth week after scarlet fever a kidney affection usually appears, without œdema or general disturbance, but with albumin, which gradually increases to a maximum and then as gradually diminishes until it disappears. Fever is likely to be present when the albumin first appears. The prognosis depends upon the degree to which the kidneys are implicated.

It can hardly be claimed for Dr. Ekkert's observations that they have solved any of the problems connected with the subject of febrile albuminuria, but as a clinical contribution to it they deserve attention. Renal congestion may so quickly lead to true nephritis, that albuminuria in fevers, or after them, should not be overlooked by the physician.

A FEVER FERMENT.

THE apostles of hot water and meat therapeutics have always made a great deal out of the yeast plant, and, in fact, based most of their pathology upon yeast and its products.

There has recently arisen a prophet of yeast in Paris by the name of M. Roussy, chief of the laboratory of the Faculty of Medicine of Paris. He has presented to the Académie de Médecine a memoir on the pathogeny of fever and the rôle played therein by the diastases or soluble ferments. M. Roussy found that sour beer and other fluids containing yeast often caused an intense fever. He found by experiment that the yeast cells produced a soluble ferment or diastase, having very powerful pyrogenetic properties. One substance in particular, which he has isolated and found to be composed of homogeneous granulations that "some tenths of a milligramme per kilogramme of animal" will induce a high fever; calls "pyretogenine." It is white, granular, homogeneous, feebly volatile, having an odor of yeast. It is hygroscopic, very soluble in water, but insoluble in alcohol. Chemically, it is an organic nitrogenized body. It has powerful properties as a diastatic ferment, turning starch into sugar, like "invertine." This latter substance, however, has no pyrotogeneous properties. M. Roussy is of opinion that this pyrotogeneous ferment which he has discovered plays a very important part in producing fevers of various kinds.

THE PROPOSED AGNEW MEMORIAL FUND.

No one was more earnest or successful in promoting the welfare of the Manhattan Eye and Ear Hospital than the late Dr. C. R. Agnew. The plan that has recently been devised, therefore, by the directors of that institution to raise a memorial fund, will, we feel sure, be universally regarded as appropriate and wise. This fund is to be used in paying the running expenses, and thus increase the usefulness of the hospital. The directors assert confidently their belief that there are many of the late Dr. Agnew's friends who will gladly contribute to this fund, to mark their sense of his own generous nature, and to aid an institution which he founded and cherished with self-denying care. It is hoped that a sum of $100,000 may be secured. It was, we are told, for many years the anxious wish of Dr. Agnew that the hospital should, for its own protection, and as a means of extension in the future, purchase the property immediately in its rear, now used as a livery stable, and which is liable to become very objectionable and detrimental to the health of the inmates of the hospital. The directors suggest that small subscriptions will be acceptable, as well as large, and that all payments can be made to suit the convenience of subscribers. We take pleasure in calling attention to the plan thus proposed, and trust that it will meet with the complete success which it deserves.

THE TOLERANCE OF IODIDES AS A DIAGNOSTIC SYMPTOM OF SYPHILIS.

A DISCUSSION has arisen between Dr. H. C. Wood and Dr. J. William White as to the fact of a special tolerance of iodides in syphilis and its diagnostic value. Dr. Wood stated that: "In all cases of doubtful diagnosis (of cerebral syphilis) the so-called therapeutic test should be employed, and if sixty grains of iodide of potassium per day fail to produce iodism, for all practical purposes the person may be considered to be a syphilitic."

From this view Dr. White dissents, and to obtain support or otherwise for his position, he has secured the opinions of a number of eminent syphilographers and general practitioners, including Professors James Stewart, James Nevins Hyde, F. N. Otis, F. R. Sturgis, McCall Anderson, E. L. Keyes, Roswell Park, R. W. Taylor, William Osler, and Drs. John P. Bryson, John B. Chapin, and E. N. Brush.

Their letters, published in *The Therapeutic Gazette* of March, 1889, represent an enormous experience in the administration of the iodides, and ought, we should say, to settle the question. Without an exception the tone of the letters is decidedly against the position taken by Dr. Wood. While some admit that in tertiary syphilis patients, as a rule, stand large doses of iodides very well, the exceptions to this rule are too numerous to make it of any diagnostic value. The general opinion seems to be that tolerance of iodides is a matter of personal idiosyncrasy, and is not modified by syphilis.

In commenting upon the letters, Dr. Wood modifies somewhat the statement we have first quoted, and says that in advanced syphilis iodide of potassium is usually tolerated much more freely than in health, and that this rule or coincidence is of sufficiently wide application to be of value in prognostication and treatment.

In the light of the evidence collected, even this proposition appears to be insufficiently supported.

A FURTHER CONTRIBUTION TO THE SUBJECT OF URÆMIA.

No subject has greater practical importance or profounder scientific interest than that connected with the pathology of urinary secretion, and more particularly that connected with the results of perturbed action of the kidneys in uræmia. We have described already the striking conclusions regarding the cause of uræmia reached by Feltz and Ritter, and by Bouchard and others of the French school. These latter results have seemed almost too precise and brilliant to be true; and as yet no positive support to their views has been made. It seems likely, however, that we will soon be reaching certainty in this line of research.

It may be remembered that a good while ago Voit called attention to the poisonous properties of the potassium salts, and thought that they might have much to do with the causation of uræmic symptoms. Voit also showed that the other constituents of the urine, though of themselves harmless in animals with healthy kidneys, could produce poisonous effects when accumulated in the body, by lessening tissue-metabolism.

In 1881 Feltz and Ritter, and during the same year, independently, Astachewsky, showed that the inorganic constituents of urine, especially the potash salts, were very poisonous. These investigators also showed that neither urea nor kreatinin caused uræmic symptoms, while the potash salts did do so. However, other experimenters soon asserted that the organic constituents of urine, as a whole, did have some toxic effect. Schiffer found that after removal of the salts one to one and a half litre of urine would kill a rabbit with spasmodic and paralytic symptoms. Bouchard found that from forty to sixty centimetres of normal urine per kilo was sufficient to kill an animal. The potash salts, he thought, caused about one-third to one-fifth of this effect (Stadthagen, *Zeitsch. für Klin. Med.*, 1889, p. 385), or, as he now says, one-fortieth part (*British Medical Journal*, 1889, p. 613). The larger part depends upon organic poisons, of which he finds no less than five.

Lepine (*Rev. de Médecine*, 1885, p. 415) comes, however, to the rescue of the potash salts. From his experiments he concludes that eighty-five per cent. of the poisonous action of urine is due to these substances.

Febrile urine he found to be more than twice as poisonous as afebrile urine—twenty-five centimetres per kilo of animal as against sixty; while the salts were relatively less toxic—forty per cent. against eighty-five per cent.

M. Stadthagen, in the *Zeitschrift f. Klin. Medicin*, Bd. xv., Hft. 5, 6, p. 387, reports the result of a fresh study of this question, following up the work of his deceased friend Dr. Schiffer. In general, Stadthagen confirms the views of Lepine regarding the toxicity of the potash salts. Furthermore, he does not think it necessary to assume the existence of any ferments or ptomaïnes, such as Bouchard discovers, in order to explain the phenomena of uræmia. These are sufficiently accounted for by the potash salts and the effect upon the system of a retention of the urea, uric acid, kreatin, etc. These nitrogeneous ingredients of the urine, while not poisonous of themselves with healthy kidneys, act as poisons when not excreted, by dampening, as it were, the processes of nutrition.

The unanimity in the results of Voit, Feltz and Ritter, Astachewsky, Lepine, and Stadthagen is sufficient to establish as a settled fact the dominant importance of the potash salts in the causation of uræmia. It seems reasonable to suppose also, with Voit and Stadthagen, that there is sufficient power of toxic action in the known organic constituents of the urine to explain the remaining phenomena of uræmic toxæmia, and for the present, at least, we can dismiss the claims of Bouchard and his five organic poisons.

A NOVEL TREATMENT OF TUBERCULOSIS.

In the case of a disease so intractable as tuberculosis it is natural enough that many and diverse methods of treatment should have been proposed, since none of those that have gone before have been shown to exert any true specific action, although some have been of undoubted utility. One of the latest of these methods, and certainly one of the most startling in its originality, is that proposed, and actually carried out in three instances, by Dr. Lanigan, of Hyde Park, Mass. This method, which is described in the *Therapeutic Gazette* for February, 1889, consists in the attempt to substitute one cachexia for another. It is, of course, only a modification of bacteriotherapy, but its peculiarity lies in the manner in which the substitution is attempted.

Dr. Lanigan says that he has for many years held a belief in the antagonism between certain cachexias. Observing that there were inherited traits of character that were diametrically opposed by others, he set about ascertaining whether there were not also antagonistic inherited cachexias, the presence of one of which would preclude the existence of the other. He believes that he has discovered such antagonism in the case of phthisis and rheumatism, for of a considerable number of cases of the former disease, in which inquiries were made in this direction, he was unable to discover a single instance in which phthisis and rheumatism had ever attacked the same individual simultaneously or consecutively. He had also observed that rheumatics were always blessed with healthy lungs.

Thinking over this apparent antagonism of cachexias, Dr. Lanigan concluded to try the effect of turning a consumptive into a rheumatic. This was accomplished by transfusion of blood taken from a patient suffering from acute rheumatism. In one case he made two injections, each of four ounces, and in a second case a single injection, of six ounces. In both instances the recipients of the blood were attacked with rheumatism within a week. In a third case, in which a single transfusion of eight ounces was made, there was a transient rise of temperature to 104° F., but no pain was experienced in the joints. All three patients improved, the temperature fell, the pulse became normal, and they increased in weight; and there is now every prospect, the author thinks, that they will continue to do well, for they are gaining strength,

have a good appetite, and seem to be on the high road to recovery.

This is satisfactory as far as it goes, but it does not go very far. The report was prepared, apparently, but a short time after the experiments were made, and the assurance of continued improvement rests only upon the hopes of the operator. Dr. Lanigan, furthermore, says nothing about the physical signs, and but little beyond what we have quoted concerning the general symptoms. The author says, however, that he will answer any questions as to this method of treatment which may be asked of him, and those desiring information concerning these missing details may obtain it by addressing him.

THE COUNTER-PRESCRIBING EVIL.

THE recent arrest of one or two druggists for usurping the functions of the physician has shown that this evil is not yet dead, and the circumstances attending these particular cases have shown no advance in the solution of the problem. The crusade has been too short-lived and spasmodic to do any good. Such instances of prosecution, occurring at irregular times, bear on them the evidences of some particular spite, rather than anything else.

The counter-prescribing practice has certain elements of permanency which we may as well recognize. In the first place is its universality. Go up and down the avenues of this city, and how many drug-stores are there in which it is not more or less done? A few, a very few on the main avenues are exceptions to this rule. In the vast majority a customer, unless he is apparently very ill, can describe his symptoms and receive therefor some medicine prepared by the druggist or sold by him in bulk. It is difficult to make degrees in counter-prescribing, and say that a druggist should be allowed to do one thing and be punished for doing another of the same essential nature. There may be less risk assumed by him in selling a cough mixture than in prescribing for a person evidently suffering from some severe fever. That, however, is the druggist's matter.

Again, the present internal revenue laws rather support the existing system. They legalize the thousand and one patent medicines. Elaborate advertising brings these to the notice of the public. The latter asks for them at the drug-stores, which, as a matter of business, must keep them. The druggist, if skilled in chemistry, can make an approximate analysis of Dr. A's pulmonic sirup. He may make, say, twenty-five cents profit from each bottle of the latter. "But," he says, "I can make a mixture of my own—practically the same thing and just as good—sell it under my own or an assumed name, and get the manufacturer's as well as the retailer's profit." This latter practice is followed in a thousand stores in this city, and how, pray, can it be prevented? The law allows the sale of the patented medicine, with certain rights reserved to its proprietors. If the druggist cares nothing for these, and is willing to risk a certain portion of his capital in the manufacture and sale of a medicine of his own, who is going to prevent him?

It is very difficult also to say just what drugs shall be considered as medicines, and what not. Many are frequently used in the various processes of domestic economy. Here the law steps in and says that a registration shall be made of the sale of certain powerful poisons which may be ordered as such, *e.g.*, morphine and strychnine. How little this law is obeyed, and how lax is its enforcement, were shown by the recent tours of the reporters of one of the morning papers, who found that in the side avenues of the city it was almost as easy to buy morphine as cream of tartar. The druggist may not sell morphine indiscriminately as such; he can, however, sell *ad libitum* cough and diarrhœa mixtures in which morphine or some other opiate is the principal ingredient. This is done every day, and it is only when some accident arises, or when some spite exists between physician and druggist, that the latter is "peached on."

We doubt not that many druggists justify these practices on the ground of the fact that, if they do not dispense medicines the patient will go to some one of the too numerous dispensaries, where he can receive his medicine for ten cents, or by lying for nothing. If he would go to an outside physician, who would prescribe, the druggist would receive the benefit; but the latter knows he will not do this, and consequently keeps him out of the dispensary by his own prescribing.

Two concluding thoughts suggest themselves: The first one is that the laws against illegal and unlicensed pharmacists should be more rigidly enforced. If those whose duty it is to guard the public in this respect fancy they have closed up all unlicensed pharmacies in New York they are most woefully mistaken. The County Medical Society has about driven out all illegal practitioners, and most commendably has this work been done. Is not also the Board of Pharmacy anxious to win an enviable reputation? The second thought is that any physician can find a practical relief from druggists' prescribing by dispensing his own medicines. We believe that the latter practice is becoming much more common, at least among those who do a general office practice. Nearly all the common remedies are now prepared in compact, tasteless, and solid form, and are therein more agreeable than many of the fluid mixtures so long in vogue. If the druggists regard this as a usurpation they have only themselves to blame.

INFECTION OF AN INFANT THROUGH THE MILK OF A TUBERCULOUS NURSE.

DR. STEIGENBERGER, of Buda-Pesth, has recorded a case of tubercular infection through the nurse's milk in the *Pesther medicinisch-chirurgische Presse.* The facts of this interesting case are summarized as follows: An infant, aged five months, of healthy parentage, developed caseating cervical, glandular abscesses, of a distinctly tubercular kind. Microscopical examination verified the macroscopical diagnosis. Inquiry elicited the fact that the infant had been nursed, for a period of four weeks, by a woman who had to be discharged on account of phthisis, with abundant expectoration. The etiological relationship was thus clearly established.

The infection of human beings through the milk of tuberculous animals has been repeatedly shown, and there is, of course, no reason why the human milk should not carry with it the same pathogenetic power. But, so far as we are aware, the above case is the first instance in which this method of transmission has been actually observed to occur. The inference is obvious, namely, to exercise the greatest possible amount of care in the selection of wet-nurses.

News of the Week.

THE NEW YORK INFANT ASYLUM.—Dr. Edmund C. Wendt has been appointed visiting physician to the above institution, vice Dr. E. Bradley, resigned.

THE AMERICAN SURGICAL ASSOCIATION.—The next annual meeting will be held in Washington, D. C., May 14, 15, and 16, 1889.

DOES NOT CARE FOR MORE GRADUATES THAN IT DESERVES.—Dr. R. G. Jennings, secretary to the Arkansas Industrial University of Little Rock, writes: "In your 'News of the Week,' April 20th issue, headed 'Medical College Commencements,' you have the Arkansas State Medical College' credited with twenty-two graduates. The 'Arkansas State Medical College' has no existence. The only medical college in the State is the Medical Department Arkansas Industrial University. This college had but seventeen graduates out of eighty-three matriculations the past session. It is evident that the Medical Department Arkansas Industrial University was the college meant in your 'News of the Week,' and as we do not desire to be credited with more graduates than we actually had, we deem it but proper to make this statement."

IOWA STATE MEDICAL SOCIETY.—The thirty-seventh annual meeting of the Iowa State Medical Society will be held at Keokuk on Wednesday, Thursday, and Friday, May 15th, 16th, and 17th, commencing on Wednesday at 10 A.M. Dr. D. Macrae, of Council Bluffs, is president of the Society.

NEW YORK POLYCLINIC.—Dr. T. R. Pooley has been appointed Professor of Ophthalmology, and Dr. B. Sachs Professor of Diseases of the Mind and Nervous System at the Polyclinic.

DR. W. M. LESZYNSKY'S CORRECTION.—In the last issue of THE RECORD in Dr. Leszynsky's article on "Localized Basal Meningitis, etc.," p. 454, line five from bottom, instead of "The pupils were equally dilated to 27 mm.," read "The pupils were equally dilated to 8 mm."

A LARGE FEE.—The fact is reported in the public press that H. M. Flagler has presented Dr. George Shelton, of New York, with securities of the par value of $50,000, market value about $87,000, in consideration of his "faithfulness and skill" in attending the case of Mr. Flagler's daughter, Mrs. Benedict, who died on her husband's yacht off Charleston, after a long illness. This is described as the largest fee but one ever paid to a physician.

A CASE OF YELLOW FEVER is reported from Sanford, Fla.

SIR EDWIN CHADWICK.—After more than sixty years of almost, if not quite, unexampled persistent labor for the public welfare, chiefly in the domain of sanitary science, and public health, Edwin Chadwick, still actively at work in the ninetieth year of his age, has been rewarded with the non-hereditary title of K.C.B., the C.B. having been conferred upon him a number of years ago.

DR. BURGGRÆVE, of dosimetric-medicine fame, is organizing an International Congress of Dosimetric Medicine, which will be held in the second week of the month of July next.

DR. HARVEY LINDSLY, the oldest physician in Washington, died at his residence in that city on April 28th, at the age of eighty-five years. Death resulted from exhaustion, due to old age. He was conscious to the moment of his death. Dr. Lindsly was born in Morris County, N. J., January 11, 1804. He was graduated at Princeton College and afterward took a course in medicine in Washington, where he was engaged in active practice until 1872, when he retired. He was an attentive and conscientious physician, and was very successful. He was elected to the Presidency of the American Medical Association at its meeting in Washington in 1858. He was at one time Professor of Obstetrics in the National Medical College, and afterward Professor of the Theory and Practice of Medicine in the same school, and was for a long time President of the Board of Health of Washington City. He was Daniel Webster's physician in the capital city. He contributed a number of valuable papers to the *American Journal of the Medical Sciences*, the *North American Review*, and the *Southern Literary Messenger*.

THE SYMBOL OSS.—At a recent meeting of the Midland Counties Chemical Association a member stated that there was some doubt as to the meaning of the symbol Oss: twenty-eight replies to an inquiry had been received from medical practitioners; twelve understood the symbol to mean eight ounces, and sixteen ten ounces. The president of the Association has in consequence addressed a letter to the General Medical Council urging it "to take such action as will relieve pharmacists from the serious difficulty under which they are now unavoidably placed." There ought, however, to be no difficulty in the matter, and the General Medical Council has already, so far as is in its power, removed all ambiguity by distinctly stating that one pint contains twenty fluid ounces, and that the symbol for it is O.

CURE OF ŒSOPHAGEAL STRICTURE.—Dr. John L. Gish, of Jackson, Mich., writes: "In your issue of April 13th, under 'Correspondence—Our Paris Letter—Stricture of Œsophagus Treated by Electrolysis,' I notice, 'that this is the first time that linear electrolysis has been applied for the cure of stricture of the œsophagus. The success is considered complete.' I wish to call your attention to 'A Case of Tumorous Stricture of the Œsophagus, with Cure by Electrolysis,' reported in full in the 'Transactions of the Michigan State Medical Society,' at Detroit, Mich., June 14 and 15, 1888, by D. S. Campbell, M.D., of Detroit, Mich. Dr. Campbell's report is the first case of which I have any knowledge."

THE THIRD CONGRESS OF THE GERMAN SOCIETY OF GYNECOLOGY will be held in the second half of Whitsunweek (June 12th to 14th), at Freiburg-in-Baden. The following communications are already announced: "Auto-infection," Drs. R. Kaltenbach and H. Fehling; "Treatment of Extra-uterine Pregnancy," Drs. R. Werth and G. Winter; "Tuberculosis of the Genital Organs," Dr. R. Werth; "Pelvic Abscess, Demonstrations of Osteoplastic Resection of the Sacrum, Tubercle of the Genitals, etc.," Dr. W. Wiedow; "Demonstration of Plastic Operations on the Genital Organs by Various Methods," Dr. E. Sonntag; "The Ovary in Uterine Fibro-myoma," Dr. A. Hölscher; "Small Cyst Degeneration of the Ovary," Dr. G.

Bulius; "Treatment of Post-partum Hemorrhage," Dr. Dührssen; "Hypertrophy of the Muscular Fibres in the Gravid Uterus—a Contribution to the Theory of the Lower Segment and Placenta Prævia," Dr. H. Bayer; "Mechanism of Respiration in New-born Infants," Dr. R. Dohrn; "Induction and Regulation of Labor by Ergot, Placentæ Circumvallatæ," Dr. Schatz. Notice of communications, etc., should be sent, up to the beginning of May, to Professor A. Hegar, Freiburg-in-Baden.

THE FOURTH MEETING OF THE FRENCH SURGICAL CONGRESS will be held at Paris, from October 7th to 13th, under the presidency of Baron Larrey. The following subjects are proposed for discussion: 1. "Results, Immediate and Remote, of Operations Performed for Local Tuberculosis." 2. "Surgical Treatment of Peritonitis." 3. "Treatment of Aneurisms of the Limbs."

HE WANTED HIS MONEY FIRST.—San Bernardino, April 17th.—At the trial of John Oakes for the murder of E. H. Morse, cashier of the San Bernardino National Bank, Cal., on December 15th last, proceedings came to a sudden halt by the following occurrence: Dr. May, of San Francisco, the expert witness, was on the stand, but he refused to answer questions till he got his pay. The court sentenced him to jail for six months for contempt. The trial was adjourned until to-morrow amid great excitement. An effort will be made to release May on a writ of *habeas corpus*.

THE CANADA MEDICAL ASSOCIATION.—The Twenty-second Annual Meeting of the Canadian Medical Association will be held at Banff, N. W. T., on August 12th, 13th, and 14th next. A cordial invitation is extended to all members of the regular profession in good standing in the Dominion of Canada, the United States, and Great Britain, to whom the necessary certificates will be sent on application to the secretary, James Bell, M.D., Montreal, Canada.

REGULATING THE PRACTICE OF MEDICINE IN MONTANA.—The Sixteenth Legislative Assembly passed an act regulating the practice of medicine in Montana, and created a Board of Medical Examiners, which are now in session in Helena, Mon.

ST. ELIZABETH HOSPITAL, NEW YORK.—The trustees of St. Elizabeth Hospital have reopened the hospital, and are prepared to receive patients. The medical branch of the institution will be under the supervision of Dr. H. Marion Sims. Patients will be nursed by the Sisters of the Third Order of St. Francis of Assisium. As yet no provision has been made for the care of male patients who are confined to bed, but physicians are at liberty to place men in charge of such patients. Patients coming to the hospital, and having no physician, will be placed under the care of the house physician, Dr. William R. Pryor. The following gentlemen compose the Consulting Board: Drs. E. L. Keyes, F. N. Otis, James B. Hunter, J. E. Janvrin, E. G. Janeway, R. C. M. Page, John A. Wyeth, H. Marion Sims, C. C. Lee.

A HOME FOR THE MEDICAL ASSOCIATION OF ALABAMA.—At a recent meeting of the State Medical Association, held at Mobile, an ordinance was introduced by Dr. B. J. Baldwin, of Montgomery, providing for the erection of a State Medical Library and Museum and Home for the State Health Officer. The object of this building is to secure to the Association a fine medical library and museum. Already some two thousand volumes have been donated as soon as the building is finished. The State Health Officer is also to have a home in this building, and he is to become the custodian of the same.

THE CONTINENTAL ANGLO AMERICAN MEDICAL SOCIETY.—The organization of the Continental Anglo-American Medical Society has proceeded so far that it has been arranged that the first general meeting shall be held on September 30th. Sir Spencer Wells, Sir Joseph Lister, Dr. Quain, Dr. Weir Mitchell, and Professors Ball and Brown-Séquard have been asked to become honorary presidents of the society. Between fifty and sixty British and American physicians have promised to join in the formation of the society. The Executive Committee consists of the following gentlemen resident in Paris: Dr. the Hon. Alan Herbert, Dr. Faure-Miller, Dr. Chapman, Dr. E. Dupuy, Dr. Barnard. The secretary is Dr. Thomas Linn, 16 Rue de la Paix, Paris.

DR. DAWBARN writes concerning an error in his recent paper: After saying that the catgut kept in ether is equally strong as that in ether and alcohol; "and iodoform is but feebly soluble in alcohol (1–80) as compared with ether (1–54)." The error here is in the last line, 1–54, which should read, 1–5.4.

THE ALKALINE BICHLORIDE TREATMENT OF YELLOW FEVER, as suggested by Dr. Sternberg, was carried out during the epidemic at Jacksonville; and Dr. Sollace Mitchell reports that it was very effective. The formula finally used was:

℞. Sodii bicarbonat..... gr. x.–lx.
Hydrarg. bichlorid..... gr. ⅓
Aquæ puræ..... ʒ iv.

M. Sig.—Give ice-cold every hour during the day, and every two hours during the night.

The bichloride had a powerful diuretic effect on the kidneys, lessening the albuminaria; the alkaline corrected the acidity of the intestinal contents.

THE STORY OF THE RAT'S TAIL is one frequently enlarged upon by physiological teachers, and it has become imprinted as a classic experiment in popular scientific literature and in standard text-books of physiology. M. Paul Bert was the original manipulator of the rat and detailer of the phenomena alleged to be produced in the ultimate appendage of the animal in question. M. Bert sewed the tip of the tail into the back of the rat. After it had taken root in its new position, he cut it off close to its original point of insertion. The rat now wore a tail reversed in position, the former tip being the root. After some time it was found that the new tail was sensitive. Conclusion, the nerves of sensation can carry impulses each way. Dr. Koch has recently performed this experiment on forty rats. In thirty cases the tails united satisfactorily, but never, even eight months later, was any sensation present in the new appendage.

"HONOUR THE PHYSITION with that honour that is due unto him, because of necessitie: for the Lord hath created him." Such is the rather perfunctory argument given by Ecclesiasticus, the son of Sirach, who adds: "The Lord has created medicines of the earth, and he that is wise will not abhorre them."

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, April 22, 1889.

ALEXANDER S. HUNTER, M.D., PRESIDENT, IN THE CHAIR.

DR. GEORGE H. FOX read a paper, entitled

THE TREATMENT OF ACNE WITHOUT ARSENIC, SULPHUR, OINTMENTS, OR LOTIONS.

He said it might be inferred from the title of his paper that he objected to the use of arsenic, sulphur, ointments, or lotions in the treatment of acne, but such was not the truth. These time-honored remedies were doubtless valuable, yet their usefulness was limited, and their routine employment was what he objected to. Some cases of acne could be cured by local treatment alone, but the majority of cases demanded general treatment; that was, the treatment of the patient, and not merely of the patient's skin. In the general treatment the administration of medicines might sometimes play an important part, but the profession had yet to learn that diet and hygienic rules were worth more than all the drugs of the Pharmacopœia. From the stand-point of the therapeutist the best division of acne was into the irritable and the indolent forms of the disease. The practical value of such a division had long been appreciated in the treatment of ulcers. The irritable form was largely reflex in origin, and was greatly affected by disturbances in the alimentary tract and of menstruation. The skin was usually fine and soft, quickly inflamed by stimulating applications, and the use of the watch-key, with which to press out the comedones, was apt to cause raised red spots. Local treatment in these cases, except of the most soothing character, was contraindicated; general treatment was most efficacious. In the indolent form the vascular excitability just mentioned was comparatively slight, while the glandular obstruction was the most important feature. The skin was likely to be coarse and doughy, often greasy. The accumulation of the foreign bodies in the skin led to the formation of the papules and pustules, and in strumous patients to abscesses. In these cases the glands should be evacuated; the skin, in other words, thoroughly cleansed. Soap and water and ointments did not answer.

Bearing in mind that the irritable form required general treatment, and the indolent form local treatment, it would be found that in the former physicians relied more upon arsenic than upon any other remedy; but he thought that if arsenic were banished from the globe the average physician would be far more successful in the treatment of acneous affections. Sulphide of calcium had been recommended by some authorities, but he thought it was liable to lead one using it to neglect more important measures. Ergot possessed value which was not generally recognized. Its chief benefit was seen in indolent acne, and he had come to regard Dr. Denbow's explanation of its action as nearer correct than that which he had formerly offered. In the local treatment of irritable acne he had tried many remedies, but would simply say that at present he seldom found occasion for their use. The treatment of acne in general, which he had found of greatest benefit, was neither new nor original; it consisted in diet and local massage. Diet struck at the root of the disease. Local massage could be made with the fingers or instruments adapted to the purpose. Its object was twofold, to empty the glands and to cause the disappearance of the inflamed lesion. It required to be persisted in. Among the instruments to be used he now felt like apologizing for his former criticism of the circular curette. Trial had proved its value, and the redness which it left would disappear in due time. No fixed plan of treatment of acne would apply to all patients.

DR. L. DUNCAN BULKLEY then read a paper on

A CLINICAL STUDY AND ANALYSIS OF CASES OF PSORIASIS AND THEIR TREATMENT.

Psoriasis being one of the most common and persistent of all the diseases of the skin, merited careful study. The author proposed to review twenty years' personal experience with it. He first briefly described it as a chronic inflammatory affection of the skin, exhibiting dry, red, slightly elevated patches or spots, varying in size and shape, generally circular, covered with a greater or less quantity of dry, white, silvery scales heaped together, and occurring chiefly on the body. As far as was known, it was always produced by the same cause, but little or nothing was known of the nature of that cause.

The disease should not be confounded with eczema, nor scaly papular syphiloderma. It rarely attacked the palms or soles. He had not seen it on the tongue. Psoriasis formed over 4.3 per cent. of all the cases of skin diseases which had come under his observation. From statistics it seemed possible varying changes in temperature, with much moisture, had something to do with the causation. Malaria had been assigned as a cause, but there were fewer cases in St. Louis than in Boston and some other cities less subject to malaria. He had treated two hundred and sixty-four cases altogether. His statistics harmonized in most respects with those of general collections. He had found that between ten and fifteen years of age the females were double the males, while between fifteen and twenty-five years of age the males were double the females. Over forty per cent. of all cases appeared before the second decade of life. The youngest patient seen by him was a little over a year of age. The course of disease was reckoned by years rather than by months or days. Over one-third of all his cases had lasted over ten years, and some as long as forty or fifty years. Many patients ceased their visits long before the eruption disappeared. Over forty per cent. of the cases remained under observation less than six months; quite a proportion of these, however, had yielded to treatment, and were apparently cured. As the disease advanced in duration a smaller proportion were benefited. But sometimes careful and continuous treatment would keep the eruption almost entirely in check even a great number of years. The natural history of the disease showed that it had scarcely any tendency to self-limitation, although its virulence was largely chargeable to the patient's carelessness; yet there were cases which proved intractable however carefully the treatment might be carried out. In a certain proportion of cases the disease was curable, the proportion depending upon the age at which it appeared, the date of commencing treatment, the character of the treatment, and the faithfulness with which it was carried out. It was most curable in children. The cases between the twentieth and twenty-fifth years were very rebellious. The treatment should include diet, general hygiene, medicinal measures, the bath, internal and external medication. Psoriasis was not a local disease, but a constitutional one, more or less akin to rheumatism and gout. Excessive meat-eating he knew to increase the disease, and the use of stimulants to precipitate an attack. Oils and fatty matters, if properly digested, favored a cure. Pure wool should be worn next the skin; sudden changes of temperature avoided; patients got along better usually in an equable climate. As to internal medication, arsenic undoubtedly caused the eruption to disappear in some cases. He had one patient who had taken probably a gallon of pure Fowler's solution in fourteen years. Alkalies were beneficial. Local applications, if used early, might prevent in a large degree development of the eruption. He had about abandoned chrysophanic acid in private practice. He had used more of white precipitate ointment in various degrees of strength than of any other local measure. A visit to mineral springs seemed to have little influence on the disease. Sulphur waters held the

best place. He had not had time to consider some other points, as heredity.

Dr. R. W. Taylor opened the discussion on the two papers. The first, he said, was a neat little paper. It savored of the iconoclastic spirit in therapeutics which was peculiar to the author, a spirit which he thought was justifiable in the present state of dermal therapeutics, and if not carried too far, leading to building up where it tore down; it was very commendable. His division of acne into irritative or hyperæmic, and indolent, was clever; it would do for discussion in a medical society. His want of faith in arsenic was in the main well founded. It could, however, be said that in some cases arsenic did good. It must be remembered that acne showed itself in so many different forms, under so many different circumstances, in so many different skins, in patients of such different habits, that it was hard to generalize in a short paper as to proper therapeutics. He thought that sufficient attention had not yet been paid the theory of the microbic origin of some cases of acne. He thought it would undoubtedly be proved that many cases were of such origin, and in that event it would not be rational to treat a follicle which contained pus, the result of an infective process from without, by a remedy presumed to act as an absorbent or disorganizer of pus when administered within. He believed Dr. Fox would find more cogent reasons for his objections to sulphuret of calcium in that direction than in any other. Ergot sometimes did good, and sometimes it did not, and might prove distressing to the patient. Massage could be used with advantage in different ways. He did not think ointments, lotions, and powders should meet with wholesale condemnation.

With regard to Dr. Bulkley's paper, it was difficult to criticise it. It followed the traditional lines of the text-books. It dealt with statistics, and all had a feeling of scepticism regarding them. They did not furnish good ground upon which to base conclusions. With respect to the question of heredity, it was generally conceded by dermatologists that psoriasis was a hereditary disease, and that this element was manifest in a measure in proportion to the intensity of the affection in the parent.

Dr. H. G. Piffard said that where Dr. Fox generalized in his paper he could agree with him, but where he particularized he could not. He said the author held acne was due more to gastro-intestinal derangement than to derangement in the genital tract. He believed the reverse was true. He had seen more cases in women due to menstrual derangement than to gastric disturbance. Acne could be of internal origin, from disturbance of the stomach, liver, etc., or of external origin, from irritation or bacteria. As to ergot, he had found, as a rule, the severer the case the more effective the drug. Sulphide of calcium was of benefit in a large number of cases, especially those of an irritable nature. Instead of administering it in minute doses, he gave as much as the stomach would bear, a quarter, half, or even a grain. In the indolent form he sought to excite the skin, whether by gymnastics or by scrubbing, powders, etc. The pustules should be evacuated, and he preferred the lancet to scraping. In all cases of acne he looked to the genital organs, and frequently found anterior stricture at the meatus an exciting cause. One patient recovered from his acne after he removed a tablespoonful of smegma from beneath the prepuce. In psoriasis he had found chrysarobin cause the eruption to disappear more quickly than any other topical agent. Arsenic should be given in full doses, continued a long time.

Dr. C. W. Allen thought he had at times seen decided benefit from sulphuret of calcium in acne. He gave it in doses of one-twentieth of a grain every two hours or oftener. As to ergot, he had seen benefit from it in women oftener than in men. If the acne were due to some chronic uterine trouble, this must first be cured. He had applied fluid extract of ergot externally, sometimes in collodion, with apparent good. The presence of one papule favored the development of others, and the physician should keep them empty from the first if possible. The chief success in acne was to come from external mechanical treatment. In psoriasis decided benefit was obtained from chrysarobin, the disagreeable effects of which were avoided by mixing it with gutta-percha. He had also employed it combined with salicylic acid with advantage.

Dr. E. B. Bronson thought Dr. Fox had not laid sufficient stress on disturbances of the genital system as a factor in acne. In the vast majority of cases the disease was aggravated by a sexual neurosis. Acne was what might be termed a developmental disease. As to removal of comedones, in many instances they might better be let alone. If the plugs could be easily dislodged it should be done. Sulphur was of decided benefit, but should not be employed indiscriminately. It was in cases marked by suppuration that this drug did most good, and he believed its action was as a germicide. In acne indurata the operative treatment was most important. Here the curette came in. As to psoriasis, he had found it almost ineradicable. Chrysarobin should supersede many of the old time topical applications, as mercurial preparations and tar. In some cases antharobin was almost equally efficacious, and did not inflame the skin unless in exceptional cases.

Dr. Sherwell, of Brooklyn, had not heard Dr. Fox's paper, but endorsed the remarks of Dr. Bronson. Acne was a developmental disease, and was closely related to the genito-urinary tract. It was much aggravated by genito-urinary irritation. Both external and internal treatment were efficacious. He spoke of criticisms made upon his experience with the passage of the urethral sound as a means of relieving acne. As to psoriasis, he believed the proportion of the cases to the whole number of cases of skin affections was not greater than three and a half per cent.; he had derived benefit from chrysarobin.

Dr. William H. Thomson, speaking from the standpoint of the general practitioner, said he had for a long time been accustomed to look to the genital organs in both sexes, and also to the gastro-intestinal tract, in the treatment of acne. Disturbances of these two tracts were often associated. In several cases of acne he had obtained benefit from a combination of benzoate of soda, naphthol, and salol. Arsenic should not be administered in acute inflammatory affections of the skin; it was useful in chronic cases. In psoriasis his favorite remedy was large doses of liquor potassa. The hereditary influence would be acknowledged by all. He believed that the majority of suppurative skin affections were of microbic origin; but in addition to exposure to the microbe it was necessary that the soil should be adapted to its growth. The skin had to be disinfected, which meant the killing of the microbe.

Dr. Jackson added his testimony to the efficacy of the curette in acne, especially of the pustular variety.

Dr. Cranmer thought dermatologists would accomplish much in the management of acne by recommending earlier marriage. When persons with acne married, their skins became clear. Some alkali was probably better than any other internal remedy. The compound decoction of aloes, although disagreeable and old-fashioned, was very useful. One of his patients, with an obstinate form of acne, obtained relief lately by a few visits to a Turkish bath.

Dr. Bulkley thought the discussion showed that in the treatment of acne the several methods mentioned were useful. He had obtained the best results, in most cases, by attention to the digestive system. He had seen many cases cured without any attention to the genito-urinary system. As to the question of marriage, many cases occurred among married people with families. It was important to clear, empty the follicles, and scrape them. As to the influence of heredity in psoriasis, among his patients he had obtained the history of one hundred and forty-three brothers and sisters, only fifteen of whom were affected by the disease, or ten per cent., while other statistics gave fifteen per cent.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON THEORY AND PRACTICE OF MEDICINE.

Statea Meeting, March 19, 1889.

R. C. M. PAGE, M.D., CHAIRMAN.

DR. HENRY LING TAYLOR read a paper (see p. 480) on

THE THERAPEUTIC VALUE OF SYSTEMATIC PASSIVE RESPIRATORY MOVEMENTS.

DR. S. BARUCH, having referred to the advantage of securing exact and positive results in therapeutics in general, said that he believed the day was just dawning for exercise as a valuable remedy. As was well known, Oertel had graduated the exercise to the type of disease in his system of mountain climbing, and admirable results had been obtained by other investigators in the same direction. Especially on account of its precision, therefore, he thought the method described by Dr. Taylor deserving of credit. It could be gauged accurately according to the circumstances in each individual case. Personally, he had had but little experience with the apparatus for passive respiratory movements, but he believed that it was based on philosophical apparatus. When a student of medicine, he became imbued with the idea that he was threatened with phthisis, and for the purpose of increasing his chest-power he had hit upon a simple device which appeared to him to be of practical utility. A long hickory stick was suspended from the limb of a tree by a rope tied around its middle, at such a height that, when he grasped it with his two hands he was obliged to stand upon tip-toe; and with this apparatus he practised daily until he was able to swing upon the stick. Later, he had employed this kind of chest-expansion not only in those in whom there was a predisposition to phthisis, but also in those in whom the disease already existed in its incipient stage, and it had been attended with satisfactory results. While it was not always possible to procure the use of apparatus such as that employed by Dr. Taylor, he thought that a great deal could be accomplished by simpler methods such as that which he had mentioned.

DR. JUDSON said that expansion of the chest by upward traction on the arms is illustrated in Sylvester's method with the drowned. He had seen an apt illustration in the dissecting-room, when a cadaver had been drawn up through a shaft by the hands fastened to a rope. The lungs being thus extremely inflated, a long-drawn sigh was heard as the subject was laid supine on the floor. Dr. Henry G. Davis, in the *American Medical Monthly* in 1856 and 1858, had called attention to the fact that the pectoral muscles make a connection between the humeri and the anterior surface of the chest, and when the arm and the anterior ends of the ribs are fixed by the hands grasping a bar overhead, the posterior ends of the ribs are forcibly drawn down by the weight of the lower part of the body, thus directly and forcibly expanding the chest. Another illustration is seen in the action of a patient suffering from asthma, who rests his hands and forearm on a table or the back of a chair to minimize the muscular effort of breathing. The respiratory brace of Dr. French, described in 1877 in the *Boston Medical and Surgical Journal*, in THE MEDICAL RECORD, is designed to support the shoulders and arms in the exhaustion of orthopnœa. The apparatus and movements described by Dr. Taylor expand the chest by traction made on the arms. I am practically familiar with their use, and confirm all that he has claimed for them. But it seems to me that much good can be obtained by carrying out the same idea, partially at least, with simpler apparatus. Nothing could more perfectly meet the indications in a case of asphyxiation from any cause than Dr. Taylor's respirator, which faithfully copies the natural respiratory movements of the chest, but simple suspension might well be used to facilitate difficult breathing, or to permanently expand the chest. With the patient seated in a suitable chair, by a slight adjustment of the body, more or less of its weightc ould be placed in suspension. Dr. Davis prescribed suspension by the hands in the treatment of lateral curvature of the spine, a very practical suggestion, because the difficulties arising from rotation, in the way of supporting the spine mechanically from the outside, make it desirable to increase in every way the contents or capacity of the chest, a reduction of which is a constant feature of asymmetry. He also advocated the treatment of phthisis pulmonalis by suspension, a practice which has a great deal to commend it from a purely mechanical point of view. I would discredit the use of the Indian club, the health lift, and similar exercises in every-day domestic gymnastics, especially for children, in favor of exercises which include suspension by the hands or shoulders. The former compress the contents of the chest in order to give a fixed point for muscular effort, while the latter join the advantages of general exercise to direct expansion of the chest.

DR. L. F. BRYSON referred to a case of lithæmic neurasthenia, in which the treatment prescribed by a number of physicians failed to afford relief. When the patient was treated by means of the Taylor apparatus, however, the mental depression which had been a most prominent feature of the trouble, was greatly benefited by the end of a month, and in six weeks this had entirely disappeared. The good results noted he believed were due to chemical changes as well as mechanical. One great advantage of the method was that, during the time the apparatus was being used, volition was abolished and thought disappeared. It was rest, exercise, and stimulus combined, and it was entirely free from certain objectionable features belonging to electricity, hypnotism, and other methods of treatment.

DR. A. B. JUDSON said that it had been known for a good many years, that suspension of the body by the hands has the power of expanding the chest, and this idea formed the basis of Sylvester's method of artificial respiration. When a student at the Jefferson Medical College, in Philadelphia, he was on one occasion in the dissecting-room at an unusual hour, and witnessed a phenomenon which he was at that time entirely unable to explain. A cadaver was being raised through a trap-door by ropes attached to the wrists and passing over a pulley, and he noticed that there was an immense expansion of the chest. When the body was placed in a supine position, however, a distinct sigh escaped from the lips, due to the expulsion of air from the chest as a result of the changed position. The explanation was perfectly plain to him when, some time afterward, he had the opportunity of reading the paper of Dr. Henry G. Davis, of this city, on the "Treatment of Deformities," published in 1854, in the *American Medical Monthly*. In this he called attention to the direct connection of the pectoral muscles with the humeri, so that when the body was suspended by the arms, the chest was forcibly drawn open, like an accordeon, and the thoracic capacity was at its utmost.

Another illustration of the same thing was shown in the attitude of patients suffering from an attack of asthma; the hands or forearms being rested on the back of a chair or other support in order to facilitate respiration. This idea was also illustrated by the respiratory brace described by Dr. French in the *Boston Medical Journal*, in 1877. It was contained, too, in the apparatus of Dr. Taylor, although the method employed was different from that of Dr. Davis, the passive respiratory movements being carried out alternately. Dr. Judson said he was familiar with the Taylor treatment, and heartily approved of all that had been said in the paper in advocacy of it. At the same time, it seemed to him that the method could be carried out sufficiently well in practice without the apparatus. Dr. Davis had also written a monogram on the curability of phthisis pulmonalis, and he was strongly convinced that suspension by the hands should constitute an important portion of all gymnastic exercises designed to assist in expanding the chest.

DR. M. P. JACOBI said that there was apparently the

same objection against Dr. Taylor's method as against the usual gymnastics, viz., that the movements imitated not normal, but abnormal, respiration, or in other words, called into action the mechanism which the organism keeps in reserve for dyspnœic respiration. In this particular it differed from the inhalation of compressed air, which exactly imitated normal respiration. During the expansion of the lung-tissue by inspiration, the centripetal fibres of the vagus were stimulated, and conveyed the impression to the respiratory centre in the medulla. When compressed air was inhaled from the Waldenburg apparatus, or when the pneumatic cabinet was employed, not only did the chest-wall rise very high, but the inspiratory movement was enlarged and prolonged, and the expiratory movement was also rendered more slow.

Dr. Jacobi then exhibited a number of tracings from the Burdon-Sanderson stethometer, taken while the patients were sitting and standing, and during natural respiration, passive movements by Sylvester's method, and inhalation of compressed air from the Waldenburg apparatus. It was evident, she said, that the expansion of the lung was much greater than in ordinary respiration when passive movements were employed; but this was still more marked when the compressed air was used, while the whole act of respiration was very much longer. Moreover, this increased amplitude of respiration was continued after the cessation of inhalation of compressed air; a fact that was never noticed after the discontinuation of the passive movements. The duration of the respiratory act was, in fact, enormously increased.

There could be no question as to the very great importance of increasing the respiratory power in many of the conditions referred to in the paper. It was not merely the size of the chest which was to be taken into consideration, but the depth and amplitude of such respiration; and it was certainly not those with the largest chests whose respiration was most satisfactory. The desired stimulus to the medulla could not be secured by passive respiratory movements. This could only be caused by the natural respiratory movements, such as characterized the inhalation of compressed air. In this natural respiration there was a direct stimulus to the vagus, and through it to the medullary centre.

Dr. W. B. Wood said that probably four-sevenths of the entire population suffered from pulmonary complaints, and the great aim of the present discussion he believed to be to determine, if possible, the best means for diminishing the present enormous mortality from phthisis. He had no doubt that there was a great deal of good in Dr. Taylor's method; but this might be equally said of a great many of the different forms of treatment which were brought forward from time to time. For his own part, he preferred to cull what was best from all that were of advantage. There were some points of importance to which Dr. Taylor had not alluded in the paper. Thus, the age of the patient, and the stage of the disease to be treated, had always to be taken into consideration. Before children were five years of age was the time when the most could be accomplished in the way of preventing phthisis in the future; but Dr. Taylor had not told us whether his method could be employed in children of five, and he was positive that it could not be resorted to in those which were only three years of age.

The stage of the disease was also a matter of the greatest importance among those who, like himself, are in the habit of constantly examining patients for treatment by means of the pneumatic cabinet. He believed that the larger their experience extended, the more it became the practice to go back to the very beginning of the trouble. What one observer would call the stage of predisposition, another, more experienced, would designate as actual phthisis. When the patient had gone to such a stage that the presence of the bacillus tuberculosis could be detected, we had one of the most difficult cases to treat that the medical practitioner ever meets, and even at the best a long up-hill task lay before us. We should endeavor, therefore, to be able to diagnose the conditions which occur antecedently to this stage.

In a general way, he said, he believed that passive movements of all kinds are more likely to develop muscle than anything else, and, furthermore, that the muscle so developed was not of the best kind. That the respiratory motions should be of a voluntary character, as Dr. Jacobi had remarked, he thought a vital point. It was by no means the man with the biggest chest and the best developed muscles who was the best breather. The stimulus needed for proper respiration was a current of air passing over the lung-tissue in such a way as to stimulate the nerves, by which the stimulus so imparted would be conveyed to the nervous centres. The bad quality of the muscle developed by massage was now quite generally recognized, and was well recognized in what was known as the "massage leg." It was too much the practice at the present day to use excessive passive exercise at the expense of voluntary exercises. From the condition brought about by such means there was always a reaction, as Dr. Taylor had himself acknowledged in the paper.

Now, whenever we had reaction, it meant an over-use of nature's power. The strength of the patient was a very important element in every instance, and he also considered that there was a good deal of risk in instituting any form of artificial inspiration until we were certain that the subject had the capacity for ordinary respiration. It should be ascertained that the nasal passages were free, and in women that the normal shape of the body had not been altered by the wearing of tight-fitting corsets. With regard to the Waldenburg apparatus, he would say that it seemed to him that there was nothing in nature which would warrant us in forcing compressed air into the lungs, since this set up a respiratory stimulus which was not normal. The pneumatic cabinet, however, was not open to this objection.

Dr. A. S. Hunter said that within the past two or three years he had had frequent occasion to note the advantages to be derived from increased respiratory capacity in various conditions, but more particularly in chloro-anæmia. The pneumatic cabinet having been brought to his notice, he had purchased one, and from his experience with it, which had been extremely satisfactory, he believed that in this apparatus we had the means of securing what we needed. All chloro-anæmics were superficial breathers, and with the pneumatic cabinet we could get a perfect and complete expansion of the chest. Under its use his patients improved in every way, and, aside from its beneficial effects on the general health, it was, to his mind, the most efficient means that had as yet been devised for increasing the respiratory power.

Dr. Kitchen said he should like to inquire of Dr. Taylor whether he used his apparatus with the intention of developing the chest-power beyond what could be used in the ordinary pursuits of the patient, or simply as a tonic and stimulus. It was a well-known fact that highly trained athletes very frequently fell victims to phthisis or cardiac disease after they ceased to engage in active muscular exercise, and he found that the over-development of the respiratory capacity would be likely to result in evil after the patients discontinued the treatment.

Dr. Quimby said that, in all such exercises as were under discussion, the fundamental point was the improvement of the general nutrition. In phthisis the bacilli were too deep-seated in the lungs to be reached by any form of medication or antisepsis, and hence any method of treatment which had this idea alone in view would prove utterly futile. We had tried the best air and other inhalations, and had only been disappointed with the results obtained. He believed, therefore, that what was needed was the employment of stimulants to the promotion of cell-action and general nutrition. This was the reason why he preferred the pneumatic cabinet to all other forms of apparatus. It accomplished all that passive exercise and compressed air from the Waldenburg cylinder did, and in addition (and what was more important) it had the ad-

vantage of clearing out bad material from the system and putting good material in its place.

In bringing the discussion to a close Dr. Taylor said that he was grateful, not less for the commendations than for the friendly criticisms on his method of treatment, which had been expressed by the various speakers. In reply to Dr. Kitchen's inquiry he would say that he did not seek to over-develop the chest, and in the class of cases in which the apparatus was called for (the patients, as a rule, being narrow-chested and possessing little respiratory capacity) he did not think that he could very well do so. In others in which he had occasion to resort to the apparatus it was not employed sufficiently long to cause any undue development.

In regard to the treatment of phthisis, he had not gone into that at all in the paper, and he certainly did not wish to be understood as recommending the apparatus in question in this disease. He referred to it in connection with phthisis merely to speak of what he believed to be its advantages in children or youths who had a hereditary predisposition to consumption. He had listened with much interest to Dr. Jacobi's remarks, and believed that all the light that could be thrown on this subject was most desirable. Without going into theoretical questions, he would only say that the practical results which had been obtained by him with the apparatus described had been very satisfactory, and he thought that this was the best proof that could be afforded of its utility.

SECTION IN SURGERY.

Stated Meeting, March 11, 1889.

ROBERT ABBE, M.D., CHAIRMAN.

PARTIAL EXCISION OF THE OS CALCIS FOR PAINFUL CICATRIX.

THE CHAIRMAN presented a man who, four years before, had sustained a lacerated wound of the heel, which resulted in destruction of considerable bone and overlying skin. The cicatrix which was left covered a conical projection of bone, and was so painful to pressure that the patient had not been able to walk during the four years. He had been successively operated upon by various surgeons, but without benefit. Seeing that an ordinary plastic operation would serve no good purpose, Dr. Abbe decided to remove the conical projection of the os calcis, and thus substitute a flat bony surface for the support of the body's weight at the heel. The result had been that the patient could walk without the slightest pain. Although a piece of minor surgery, the operation was a very important one, for cicatrices of the heel, as well as ulcers of the foot, if tender, were ordinarily considered beyond remedy.

HYSTERICAL MYOCLONUS MULTIPLEX IN A MALE.

The Chairman also presented a man in his twenties, who after sustaining a sharp pain in the back from a violent effort to save himself from a fall, claimed to lose power and sensation in the right leg. Pricking with the pin caused apparently no pain. He had also myoclonus multiplex, or clonic spasm, in groups of muscles in various parts of the body. For instance, when the muscles of the neck became spasmodically contracted, it appeared as if the head would be jerked off. An hysterical condition immediately suggested itself, and was proven to exist by placing the patient partially under the influence of ether, when power in the legs quickly manifested itself. The patient had also claimed to have a single painful point in the spine, but by suggestion as many as ten pretended painful points were brought out. One day, when rudely pushed across the floor and roughly treated, his difficulty in walking quite disappeared. Dr. Abbe thought the patient was not a malingerer, but a hysteric.

MODIFIED TRACHEOTOMY.

DR. D. BRYSON DELAVAN described a modified tracheotomy which he first performed several years ago in a case of cancer of the larynx. Since then he had performed the operation a number of times, and had found it a valuable procedure, and inasmuch as his first description of it had not received the attention he thought it deserved, he wished again to call attention to it. The method was more particularly adapted to conditions of the larynx in adults requiring the prolonged use of a tracheotomy tube. In adults the cartilaginous rings of the trachea became hard and less resilient, and when a simple incision was made, as in tracheotomy, there was some difficulty in introducing the tube, and unless the wound were held gaping by means of a pair of forceps, there was danger of doing violence to the parts while pushing in the tube. After the tube had been worn for some time (as was necessary in cases of obstruction from cancer, etc.) absorption of the tissues immediately around it took place, and left a hole through which the tube could be introduced without force or irritation. Dr. Delavan obtained this desired result immediately by cutting out a round opening, including a part of two cartilaginous rings, in the adult. This form of opening not only facilitated introduction of the tube, but avoided irritation by pressure of the separated walls upon the tube, and also bulging forward of the posterior segment of the trachea. In reply to the Chairman, whether a fistula was likely to remain, Dr. Delavan said that in these cases the tube usually had to be worn the remainder of life. If only a vertical incision were made, the wearing of the tube for some time would anyway result in absorption of tissues and an opening of similar form.

MORBUS COXARIUS.

DR. V. P. GIBNEY presented, at the close of the meeting, sections of the head of the femur and acetabulum illustrating the early stage of morbus coxarius, before the formation of pus, and expressed the opinion that it was of tubercular origin. The boy, aged twelve, had died of tubercular meningitis.

DR. W. W. VAN ARSDALE read the paper of the evening,

SUBLUXATION OF THE HEAD OF THE RADIUS IN CHILDREN, WITH A RÉSUMÉ OF 100 CONSECUTIVE CASES.

The lesion, he said, is generally seen under the following conditions: The child is brought by the mother, complaining of pain at the wrist and inability to use the arm. The child lets the arm hang motionless at the side, slightly flexed at the elbow, the hand midway between pronation and supination. The mother says that when leading the child by the hand it stumbled, and in her effort to save it from a fall she jerked the hand upward. At this moment she felt a click at the wrist and the child cried out in pain. Although the child did not fall, it has not used the hand since.

On examination, everything about the hand is found normal; the movements at the wrist free and not painful. Abduction, adduction, and extension are made passively without resistance. The elbow reveals no deformity whatever. The head of the radius, too, appears to be in place. At this time in the examination the first abnormal symptom is discovered. Pressure, even if slight, on the head of the radius is painful, and if the forearm be flexed beyond sixty degrees it is checked by the efforts of the child, owing to pain. The child never supports the arm with the injured one, as is the case in injuries to the shoulder. Complete pronation is possible, but somewhat resisted; supination, however, causes the child to cry out with pain and actively resist motion. There also appears to be some mechanical resistance to supination. Forcing supination still farther, a distinct click is felt at the elbow, or more directly at the head of the radius, after which all the movements of the arm at once become free and apparently cause no more pain. One symptom, however, still remains. Direct pressure on the head of the radius causes pain. In two or three days the child may be brought back, with swelling at the elbow-joint and all the

symptoms just described aggravated, because of recurrence of the subluxation. If, however, the arm is put up, the elbow flexed at a right angle, the hand midway between pronation and supination, the mother will say at the end of three or four days that the hand must be well, as the child complains no more, and on removal of the bandage the arm will be found normal, and active and passive movements free.

Such was the clinical picture of a condition which the author had described as subluxation of the head of the radius, and which had been called by various writers, partial dislocation of the radius, dislocation downward by elongation, etc. The injury was not a dislocation as that term was usually employed, as there was no extensive rupture of ligaments, nor were the articulating surfaces of the bone forced from their normal position to any great extent. The injury was slight, but always occurred in the same typical manner, which fact should place it as a distinct lesion, and it had been so recognized by a long line of observers. While it had been frequently made the subject of careful inquiry, yet it was not well understood, nor was it so widely known as at times not to escape detection. About seventy articles had been written on the subject, mostly in periodical literature. Fournier, 1671, first called attention to it; about four hundred cases had been described altogether, yet among injuries at the elbow this one was comparatively frequent.

Strumous diathesis had been frequently mentioned as a predisposing cause. Overwhelming testimony was in favor of traction on the hand or forearm as the exciting cause. The greatest harmony prevailed regarding the symptomatology.

The mystery surrounding the lesion was due chiefly to the click or snap heard on supination of the arm. To account for this different theories of the nature of the lesion had been advanced. Many writers believed the lesion consisted in a slight and incomplete anterior displacement of the head of the radius, with stretching of the ligament. Some thought it due to contraction of the biceps partially dislocating the head of the radius backward; a view which Dr. Van Arsdale had convinced himself was erroneous, as the biceps in the child was not strong enough to alone produce the lesion. The view which had gained most in favor was that of partial dislocation from extension. But why in this case should the injury persist? Because, according to Streubel, whose explanation had been accepted by many, of folding in of the orbicular ligament. Proof of this explanation was based on cadaver experiments; but inasmuch as there was loss of muscular tone after death, this test was not altogether convincing. Dr. Van Arsdale had been unable, by experimental and clinical study, to satisfy himself of the exact nature of the lesion. There were scarcely any records of post-mortem examinations.

The author's hundred cases were treated at the dispensary. They were exclusive of thirty doubtful ones. The average age was two years and one-fourth. Many of the children were badly nourished, while others were robust, of healthy parents. In some, undoubted signs of rickets were present; tubercular constitution was not general. The exciting cause was some violent traction of the hand or forearm. No displacement could be felt. During reduction, with the thumb placed over the head of the radius, the jar was felt to be lateral, not longitudinal, when the snap from replacement was heard. In a number of cases the click could not be heard; while in others it could be repeated twice or even three times. The after-treatment consisted in the use of a single pasteboard box splint, the hand kept in a sling perhaps five days.

THE CHAIRMAN, in stating that the paper was open for discussion, remarked that some years ago he had roughly estimated the total number of surgical cases seen by him to be over twenty thousand; yet he had not seen this particular lesion, or, at least, had made no note of it.

DR. V. P. GIBNEY had seen very few cases. The lesion might possibly be mistaken for the early stage of osteitis, yet the history of the case would probably readily settle the diagnosis.

DR. KOPLIK had seen a great many of the cases included in Dr. Van Arsdale's list. The lesion was typical, and there could be no mistake about its recognition. The two principal diagnostic points were paresis and pain on manipulation of the forearm. He thought there was a rachitic tendency in many of the cases seen by Dr. Van Arsdale; it was probably present in some cases, and yet presented no marked outward manifestation. He was disposed to think some such predisposition usually existed in addition to the exciting mechanical cause. He thought the theories of Fournier and Chassaignac went a long way to explain the symptoms.

DR. A. B. JUDSON had seen but one case, and in that instance the lesion seemed subsequently to have spontaneously disappeared.

DR. C. A. POWERS said his attention was first called to this class of cases in 1885, and during the two years ending May last, he saw 15 cases at the Chambers Street Hospital. The entire number of recent injuries treated at the hospital during that time was 25,000. Of the 15 cases, 12 were in children, 3 in adults. The symptoms were typical—disability, pain over the head of the radius, and a distinct snap on reduction. It was a snap rather than a click. As a rule, the history of the injury was indefinite. In a considerable number the parents had heard a distinct click at the elbow or wrist at the time of the injury. The cases in adults gave him more concern than those in children. In the latter he kept the arm quiet two or three weeks after reduction. There was no recurrence, no disability. In the adults pain and dis ability at the elbow persisted two or three months—a much longer time than would be expected from so slight an injury.

DR. POWERS thought the theory of longitudinal fracture through the head of the radius was not tenable. In one case, that of a child three years of age, there was a distinct history of lifting by the hand as the cause of the injury, and he felt positive the lesion was a diastasis at the neck of the radius. He could easily grasp the head of the radius between the thumb and forefinger, and on pronating and supinating the forearm he was certain that the head did not move; and there was soft crepitus. One would suppose separation between the neck and head of the radius might be more frequent.

DR. VAN ARSDALE said, in reply to Dr. Gibney's question, that he thought no serious consequence followed in cases not treated. There were several reasons why more of these cases were seen in dispensary practice than in hospitals or private practice; the chief ones being the comparative insignificance of the lesion and free treatment at the dispensary. He could not agree with Dr. Koplik, that the paresis was not due to pain. As to diastasis at the neck of the radius, when this lesion existed it could readily be determined by the greater mobility and crepitation.

THE PRESCRIPTION.—There was, some time ago, a doctor whose morning levees were crowded beyond description. It was his pride and boast that he could feel his patient's pulse, look at his tongue, probe at him with his stethoscope, write his prescription, pocket his fee, in a space of time varying from two to five minutes. One day an army man was shown into the consulting room, and underwent what may be called the instantaneous process. When it was completed the patient shook hands heartily with the doctor, and said: "I am especially glad to meet you, as I have often heard my father, Colonel Forester, speak of his old friend Dr. L." "What!" exclaimed the doctor, "are you Dick Forester's son?" "Most certainly I am." "My dear fellow, fling that infernal prescription into the fire, and sit down quietly and tell me what's the matter with you."—*Murray's Magazine.*

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 21 to April 27, 1889.

MAGRUDER, DAVID L., Colonel and Surgeon. By direction of the Secretary of War, his retirement from active service this date, by operation of law, under the provisions of the act of Congress, approved June 30, 1882, is announced. Par. 4, S. O. 94, A. G. O., April 23, 1889.

VOLLUM, EDWARD F., Colonel and Surgeon. Promoted to Surgeon, with rank of Colonel, from April 23, 1889.

WRIGHT, JOSEPH P., Lieutenant-Colonel and Surgeon. Promoted to Surgeon, with rank of Lieutenant-Colonel, from April 23, 1889.

WOODRUFF, EZRA, Major and Surgeon. Promoted to Surgeon, with rank of Major, from April 23, 1889.

WHITE, ROBERT H., Major and Surgeon; EWEN, CLARENCE, Captain and Assistant Surgeon; COCHRAN, JOHN J., Captain and Assistant Surgeon; and EWING, CHARLES B., First Lieutenant and Assistant Surgeon. Pursuant to instructions contained in letter from Adjutant-General's Office, Washington, April 13th, the above-named medical officers will assemble with troops in New York Harbor, on the 27th instant, prepared for field service in connection with the New York Centennial parade. S. O. 90, Headquarters Division of the Atlantic, Governor's Island, New York City, April 19, 1889.

WALKER, FREEMAN V., First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, leave of absence for four months on surgeon's certificate of disability, with permission to leave the Department of Texas, is granted him. Par. 12, S. O. 92, A. G. O., April 20, 1889.

WOODRUFF, EZRA, Captain and Assistant Surgeon. By direction of the Secretary of War, relieved from duty at Fort Missoula, Mont., and to report in person to the Commanding Officer, Fort Monroe, Va., for temporary duty at that post. Par. 14, S. O. 72, A. G. O., April 20, 1889.

HAVARD, VALERY, Assistant Surgeon. Relieved from duty at Fort A. Lincoln, Dak., and ordered to Fort Buford, Dak.

CRAMPTON, L. W., Assistant Surgeon. Relieved from Fort Bridger, Wyo., and ordered to Fort Lyon, Col.

SPENCER, W. G., Assistant Surgeon. Relieved from Fort Yates, Dak., and ordered to Fort Bridger, Wyo.

ROBERTSON, R. L., Assistant Surgeon. Relieved from Fort Buford, Dak., and ordered to Fort A. Lincoln, Dak. Par. 29, S. O. 95, A. G. O., April 24, 1889.

Official List of Changes in the Medical Corps of the United States Navy for the week ending April 27, 1889.

WILSON, GEORGE B., Assistant Surgeon. Detached from the Naval Hospital, Mare Island, and to the Iroquois.

CORDEIRO, F. J. B., Passed Assistant Surgeon. Detached from the Vandalia, and to the Naval Hospital, Mare Island, Cal.

BRANSFORD, JOHN F., Surgeon. Ordered to the Iroquois.

STITT, EDWARD R., Assistant Surgeon. Ordered to the Bureau of Medicine and Surgery, Washington, D. C.

FEREBER, N. M., Surgeon. Ordered to Naval Academy, Annapolis, Md., for examination of candidates for admission to the Academy.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 27, 1889:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	10	3
Scarlet fever	378	49
Cerebro-spinal meningitis	5	4
Measles	196	10
Diphtheria	201	57
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

THE NETTLE AS A THERAPEUTIC AGENT.—In the *Meditzinskoiĕ Obozrenië*, No. 16, 1888, p. 330, Dr. Vladislav A. Frankowski, of Kharkov, whose medical experience embraces about one hundred thousand cases, speaks enthusiastically of "urtication," that is to say, slapping or pricking with a bundle of fresh nettle-twigs, for one or several minutes, once or several times a day, as an excellent epispastic application. It has considerable advantages over ordinary derivative remedies, inasmuch as it is quite innocuous (not irritating the kidney, and leaving no permanent marks on the skin, etc.), cleanly, simple in application, rapid in its effect, and cheap. Dr. Frankowski recommends it especially in (*a*) anæsthesia, paralysis, and neuralgia, especially sciatica of peripheral origin, as well as in incipient tabes, where he applies the nettles directly to the parts affected; (*b*) in dyspnœa depending upon cardiac or vascular disease, where "general urtication" (that is, pricking along the vertebral column and over the whole abdomen and chest) is said to "relieve the agonizing symptoms far more rapidly and more completely than any other epispastic does;" (*c*) in respiratory diseases, spinal and thoracic urtication soon allays cough, promotes expectoration, relieves oppression, and produces a striking, though only temporary, improvement in the subjective condition; (*d*) in amenorrhœa, urtication of the lumbar, sacral, and internal femoral regions excites the menstrual flow, even when employed alone, without any adjuvant; (*e*) in impotence, pricking the loins, sacral region, and genital parts is also of great service; (*f*) in rheumatic, muscular, and articular pains, urtication, combined with cold bathing, is often far more useful than anything else; (*g*) in syncope, asphyxia, concussion of the brain, coma, etc., energetic general urtication is an invaluable resuscitating measure which has been successfully resorted to by the peasantry all over Russia from time immemorial.—*Brit. Med. Journal.*

A MODIFIED SCUDDER'S KNOT-TIER.—Dr. J. T. Crow, of Carrollton, Ill., sends us a model of a modification of the knot-tier described by Dr. Scudder in THE MEDICAL RECORD of March 16th. It is made of a simple piece of copper wire, twisted to form the handle, with the two ends diverging as in the original instrument and bent over at their extremities so as to form eyelets, through which the ligature is passed. It can be made of any kind of wire, and may be nickel or silver plated. The handle may be encased in rubber or wrapped with a piece of muslin to give it more bulk, if desired. The eyes can be given any inclination desired by bending the jaws up or down. The modification can be made much more cheaply than the original, or in fact can be constructed by the surgeon himself out of a piece of wire, with the aid of a pair of nippers.

A HUNDRED YEARS HENCE all we may be doing now may be nothing more than curious history.

PROFESSOR VIRCHOW AND HOMŒOPATHY.—A case of much interest, especially in connection with the cancer of the larynx and the case of the late Emperor of Germany, has recently been reported (*Lancet*). Professor Virchow writes to the *Deutsch Med. Wochensch.* as follows: "In December, 1888, a letter of thanks from a patient to a homœopathist was published in a local paper, ascribing to the latter the cure of a severe disease of the larynx which had been recognized by Berlin specialists and by me as cancer. This letter of thanks has been circulated far and wide, especially in the provincial press, and has induced several physicians to address questions to me and letters, with the request that I would enlighten the public by communicating the real facts of the case. In view of this public and professional interest in the matter I think it right to make the following statement: It is true that the patient, a man of sixty-eight, was examined with the laryngoscope by Professor Krause's assistant, Dr. Friedländer, on December 7, 1887, in Professor Krause's absence, and found to be suffering from cancer in the larynx. The growth, as far as it was visible, was removed by Dr. Friedländer through the mouth next day, and brought to me for microscopic examination. I confirmed the diagnosis. A recent examination of the still existing remnants of the growth yielded the same result. I am credibly informed that the patient did not consent to the partial extirpation of the larynx which was proposed to him, but went home and wrote to a homœopathist, who, without ever seeing him before or after, sent him his advice and remedies by post. The patient was re-examined by Dr. Krause a few days ago, Dr. Friedländer being ill. Dr. Krause ascertained that no cure has taken place. Though at this moment—that is, more than fourteen months after the endo-laryngeal extirpation of the growth—the patient suffers no pain or obstruction except lasting hoarseness, the examination with the laryngoscope showed that the disease remains unchanged."

THE PEANUT IN THERAPEUTICS.—The peanut, beloved of the gods—of the gallery, may possibly vindicate its claims to popularity, as it is recommended as a remedy for insomnia. It is said to be quite efficacious when taken *ad lib.*, freshly roasted, before retiring. It is true the recommendation is made by a clergyman, but as it is not a new tonic made from bad whiskey, an opium cure containing morphine, or any of the other blessings to humanity usually floated on clergymen's endorsements, we need not condemn the peanut without a trial. It is certain that the free use of this nut sometimes produces vertigo and slight mental exhilaration.—*Philadelphia Medical Times.*

A NEW METHOD OF PERFORMING URANOPLASTY.—At a recent meeting of the Society of Physicians of Vienna, Professor Billroth showed four patients on whom he had performed staphyllorraphy and uranoplasty, by a new method, at one sitting, with much success. Uranoplasty had been introduced into surgery by von Langenbeck, and Professor Billroth had modified the procedure to meet the following conditions: The nasal was shut off from the pharyngeal cavity during speech not only by the application of the soft palate to the posterior wall of the pharynx, but by the action of a circular muscle, the anterior part of which was contained in the velum. This muscle acted as a sort of sphincter, and the results hitherto obtained in operations for defects in the soft and the hard palate were not quite satisfactory, owing to the fact that this sphincter was cut through when the velum was divided. In cases of extensive cleft palate there was a congenital defect not only in the bone but also in the sphincter of the velum, and if the remaining portion of this muscle was cut through, occlusion became impossible and speech was much impaired. Professor Billroth, therefore, only divided the mucous membrane at the side of the velum, and approximated the internal wings of the sphenoid to each other by means of the chisel. The mucous membrane was utilized to cover the defect, and the sphincter remained intact. Dr. Coën, of Vienna, had put the patients through some exercises of speech with considerable success, though the time was too short for really good results to be obtained. Dr. Coën made them go through some speech-exercises before the Society, and pointed out that there was special difficulty in the production of sounds in the posterior part of the oral cavity. The pronunciation of the "g" was the most difficult. Their speech was, however, generally, intelligible. Professor Exner remarked that such patients had not only to learn how to speak, like little children, but that they must also forget their previous speech; they must forget their previous innervation sensations and try to acquire new ones.—*British Medical Journal.*

A JUDGE'S OPINION ON THE USE OF THE TITLE HOMŒOPATHIST.—Judge George C. Barrett, of the Supreme Court of this city, sends to the *New York Medical Times*, an opinion which will be read with much interest. He was asked to give a reply to the question: "Has a physician designating himself an 'Homœopathist' and called as such to a patient, any legal or moral right to adopt other than homœopathic means in the treatment of the case?" To this Judge Barrett answers: "I have your note of the 11th inst., asking my opinion upon a question of professional ethics. In my judgment there can be but one answer to your question, and that is in the negative. If I call in a medical man who designates himself a 'homœopathic physician,' it is because I do not wish to be treated allopathically, or eclectically, or otherwise than homœopathically. There is an implied understanding between myself and the homœopathist that I shall receive the treatment which, by tradition and a general consensus of opinion, means small doses of a single drug administered upon the principle of *similia similibus curantur*. If there is to be any variation from that method I have a right to be informed of it and to be given an opportunity to decide. Common honesty demands that before a confiding patient is to be drugged with quinine, iron, morphine, or other medicaments, either singly or in combination, he should be told that the 'homœopathist' has failed, and that relief can only be afforded by a change of system. An honest 'homœopath,' who has not succeeded, after doing his best with the appropriate homœopathic remedies administered on homœopathic principles, should undoubtedly try anything else which he believes may save or relieve his patient. But when he reaches that point the duty of taking the patient into his confidence becomes imperative. The patient may refuse to submit to the other system or he may agree, but prefers a physician whose life has been specially devoted to practice under that other system. He may say to the 'homœopathist:' You have failed, but I prefer to try another gentleman of your own school, before resorting to a system that I have long since turned my back upon. Or he may say, Well, if homœopathy cannot save me, I prefer to go to headquarters for allopathic treatment. All this, gentlemen, is the logical sequence of the particular designation 'Homœopathist.'"

HYSTERIA IN THE RUSSIAN ARMY.—According to Dr. Ozeretskofski, of Moscow, the existence of hysteria among Russian soldiers is by no means an exceptional occurrence. The affection presents the same diversities of form that it does among women. Frequently men suffering from this affection are put down as malingerers. Other cases are looked upon as instances of serious but somewhat obscure organic disease, the true nature of the case being nearly always overlooked, because it is not generally supposed that soldiers are liable to hysteria. So real, however, does Dr. Ozeretskofski consider the existence of this male hysteria, that, having had an opportunity of studying no less than thirty-eight cases in the Moscow Military Hospital, he is convinced that hysteria ought to be recognized as one of the affections which entitle the subject of it to exemption from military service.—*The Lancet*, February 16, 1889.

Original Lectures.

THE PLANS AND PURPOSES OF THE JOHNS HOPKINS HOSPITAL.[1]

BY JOHN S. BILLINGS, M.D.,

SURGEON U. S. ARMY.

THE third paragraph of the letter of instructions communicated by Johns Hopkins to the trustees whom he had chosen to carry out his plans for a hospital in the city of Baltimore states that "it is my wish that the plan . . . shall provide for a hospital which shall, in structure and arrangement, compare favorably with any other institution of like character in this country or in Europe." What do you suppose the writer was thinking of when he penned that sentence? Had he in view any definite ideal, any mental picture of the institution which he proposed to establish, or was it merely an expression of a desire to give to his city the best thing that could be devised? I have read that letter many times, have heard much of the ideas, hopes, and wishes which were expressed in the numerous conversations which preceded its preparation, and it seems to me that the writer had an ideal, and not a mere vague desire—an ideal which was no doubt somewhat misty, but which did not correspond to any existing hospital, and one which he did not attempt to define except in a few prominent points to which I shall presently refer. In most respects Johns Hopkins took the same course with his hospital which he did with his university, and deliberately refused to trammel with specific directions those whom he had chosen to carry out his plans; but this letter of instructions indicates, nevertheless, a conception of much more definite character, and one which had been the subject of more discussion and reflection than his scheme for a university. Whether this be so or not, I am at all events sure that his trustees have endeavored to comply with this letter of instructions, and to do so in the broadest and best sense of the words.

The beginning of the results we have before us to day; results which even now are not confined to these particular aggregations of bricks and mortar, as will be presently explained, and the end of which will be, as we hope and believe, to make life happier for millions now living and yet unborn. Only those who took part in the early deliberations of those charged with this trust can fully realize the anxieties, the doubts, the manifold perplexities which at first attended their decisions and movements. Only one or two of them had any knowledge of hospital matters; most of them were business men, bankers, lawyers, judges, railway managers, men who knew something of the management of men and money, but who were now brought face to face with a new problem, viz., how to build, organize, and manage a hospital so that it should compare favorably with any other hospital in this country or in Europe.

To "compare favorably with," what does that mean? It is a peculiar phrase, which, coming from a shrewd business man and a member of the Society of Friends, signifies, I think, to excel, if possible; at all events, that is the safest interpretation. And it was not this or that hospital which was to be surpassed or equalled, but all other hospitals in this country or in Europe; Africa, Asia, and Australasia being put out of the question. It was a large contract.

The location was fixed—that had been done by Johns Hopkins, but they had to decide whether the structures to be erected should be temporary or permanent, of wood, brick, or marble, in one large building or in many, and many other like points, before even the preparation of plans could be commenced. They followed the instructions of the donor and got advice, of which a great abundance was available. They visited the large hospitals of our Eastern cities, employed five men, supposed to be skilled in hospitals, each to write an essay giving his plans and suggestions, published these essays in a book which had a wide circulation, and studied the criticisms and reviews to which this book gave rise.

Having duly considered the multifarious and widely divergent suggestions thus obtained, they finally selected one of the essay-writers and asked him if he was satisfied with his own plans now that he had seen the others and the published criticisms upon them. He promptly said that he was not, whereupon they asked him to try again and do better. He set to work, aided by the architect of the Board, and the result was a set of sketch plans which he took abroad and obtained much counsel and criticism on, examining at the same time the model hospitals of Europe. He was much less satisfied with the sketch plans when he came back than he was when he started, and again the Building Committee, the architect, and himself reviewed the whole matter, and finally settled on the general arrangement which you will see to day. Many details remained to be worked out; even the façades had not yet been designed; but the general scheme was settled, and the rest was comparatively easy for the time being.

Let us now, for a few moments, consider the broad general principles which governed the trustees in the adoption of this plan. The first hospitals were established to give shelter and food to the sick poor, especially those who gather in cities. Gradually physicians found that they could learn much in these aggregations of suffering, and that they afforded means of teaching others; but this last use of them is only about two hundred years old. Gradually, also, it came to be known that the knowledge thus obtained in the care of the sick poor was of use in treating the diseases of the well-to-do; and, finally, within the last twenty-five years or so, people are beginning to find out that when they are afflicted with certain forms of disease or injury they can be better treated in a properly appointed hospital than they can be in their own homes, no matter how costly or luxurious these may be. In the hospital they can have not only all the comforts of home, but more; not only skilled medical attendance and skilled nursing, but the use of many appliances and arrangements specially devised for the comfort and welfare of the sick which can hardly be found in any private house, and also freedom from noise and many petty annoyances, including in some cases too much sympathy and in others too little. This hospital, then, is to provide for the rich as well as for the poor; for those who can, and ought to pay for the help given as well as for those who cannot.

A second cardinal principle to be observed in such a hospital as this, is that it shall do as little harm as possible. A hospital may do harm by its foul air, by spreading contagious disease among its inmates, by neglect or

[1] An address delivered at the opening of the hospital, May 7, 1889.

carelessness of its nurses or attendants; and in years gone by hospitals have, no doubt, caused nearly as much sickness as they have relieved. This is now rarely the case, and in this hospital the arrangements for ventilation, isolation, and nursing are such as to entirely do away with this danger. There is another danger connected with free hospitals and dispensaries which is of quite a different kind and to which I can here only allude—namely, the danger of promoting negligence, shiftlessness, laziness, and vice by offering free relief from their consequences—the danger of pauperizing people. This is a danger connected with organization and management rather than with construction, and I can only say here that it has been foreseen, and will be, as far as possible, guarded against.

The third principle to be kept in view in such a hospital as this, is that it should provide the means of giving medical instruction, for the sake of the sick in the institution as well as of those out of it. It is well known to those familiar with the subject that the sick in a hospital where medical instruction is given receive more constant, careful, and thoughtful attention than do those in a hospital where no such instruction is given. The clinical teacher must do his best; keen eyes will note every error in diagnosis, every failure in results of treatment. Moreover, the very act of teaching clarifies and crystallizes his own knowledge; in attempting to explain, the dark places become prominent and demand investigation, and hence it is that those cases which are lectured on receive the best treatment. I need say nothing here on the other side of the question, the value of properly trained physicians to the community and the necessity for hospital instruction in such training. Johns Hopkins understood all this and specially directed that "in all your arrangements in relation to this hospital you will bear constantly in mind that it is my wish and purpose that the institution shall ultimately form a part of the medical school of the university."

Now there are medical schools and medical schools, and in obeying this direction of the donor the trustees had to consider what sort of a medical school this school of the university was likely to be. As the majority of the trustees were also trustees of the university, they knew well the principles which underlie the organization of that institution and that the same principles would govern the organization of the medical department when that came to be taken in hand. One of these principles is the thorough teaching of that which is known, another is to increase that which is known, and to furnish the men and means for doing this. So also the hospital should not only teach the best methods of caring for the sick now known, but aim to increase knowledge and thus benefit the whole world by its diffusion. Another point which had to be kept in view was the direction of Mr. Hopkins that there should be established, "in connection with the hospital, a training school for female nurses, not only to care for the sick in the hospital but to benefit the whole community by supplying it with a class of trained and experienced nurses."

It is also highly desirable that a hospital of this kind should have connected with it a well-appointed dispensary for the treatment of those who need medical aid but not a bed in the hospital. Through such a dispensary much good can be done at small cost, the selection of proper patients for the hospital is facilitated, the means of medical investigation and teaching are greatly extended, and the scope of the nursing system can be made to reach the poor and ignorant in their own homes.

The last point to which I shall refer, which was kept in view by the trustees in deciding upon the plans, was the general appearance of the buildings and grounds.

Mr. Hopkins gave no specific directions as to the buildings, but he directed that the grounds should be properly enclosed by iron railings, and so laid out and planted as to be a solace to the sick and an ornament to the city, and it was evident that the buildings should be of the same character so far as their purpose would admit. It was therefore decided that, while no utility should be sacrificed for the sake of architectural ornament, and the main purpose which I have referred to should be fully worked out in the plans before any attention was paid to external appearance, it was fit and proper that the buildings should form an ornament to the city, and a suitable monument to the memory of the donor.

Bearing in mind, then, these main principles, to provide for the proper care of the sick, both rich and poor, to provide for the highest class of medical education, to increase and diffuse knowledge, to provide trained nurses for both hospital and city, to provide a dispensary, and to make the buildings and grounds ornamental and attractive, let us see how the problem has been thus far worked out.

I will begin with the arrangements for securing that article of prime necessity in a hospital, viz., pure air. Air-supply and ventilation in this climate are inseparably connected with heating for a considerable portion of the year, for comfortable warmth must be secured, and on the means of doing this must largely depend the methods of ventilation and their success. The temperature of Baltimore may vary from 103° in the shade to 17° below zero, F., hence its perfect hospital must be one which would answer for the tropics or for Northern Russia. To secure this, double walls, with air-spaces, were given to the buildings, and a system of heating by the circulation of hot water was adopted for the wards. This system consists of central boilers, from which flow and return pipes extend beneath every building, connected with heating coils, of which there is one for every two beds in the ward above. The temperature in these coils can be exactly regulated to any temperature between 150° F. and the temperature of the external air by simply regulating the velocity of the flow of water by the valves attached to each coil, and thus it is quite possible to give one pair of beds a temperature of 70° and another pair in the same room, at a little distance, a temperature of 60° F., to suit the needs of different cases. The 80,000 gallons of water contained in this heating apparatus go round and round, carrying heat from the furnaces to the wards, but every building has its own independent means of ventilation, and it is not possible to go from one ward into another without going into the open air on the way, so that foul air, if any forms, cannot spread from one building to another. Nevertheless, the buildings are so connected by corridors and underground tunnels that in passing from one to another there is no exposure to rain or snow, and the least possible to cold air, while the food is not exposed at all. This is not the place to describe the ventilation. I will only call your attention to the fact that the temperature of the incoming air by any bed is easily changed by turning a valve, while the quantity of air is not changed; to the arrangement for taking foul air from either the bottom or top of the ward, or from both, and to the fact that all this has been thoroughly tested during two winters and found to give the results hoped for.

One of the peculiarities of the wards is that all the service rooms are collected at the north end, leaving the south end free of obstruction and fully exposed to the sun, the end of the ward being a large bay window looking out on the central garden, and with a floor which can be warmed so that the patients able to sit there can be thoroughly comfortable. Another peculiarity of the sick wards is the arrangements for easy cleansing, and to prevent possible accumulations of dust in corners and crevices. Corners are to a great extent done away with, and easy curves given in their place; even at the junction of the floor and walls there is a curve instead of the usual right angle, and I advise you to look at it and see how it has been produced, for it ought to become fashionable, and take the place of the old mop-board in all well-constructed houses. So, also, the doors have not the usual moulding about the panels, giving recesses which it is almost impossible to clean.

One of the wards is especially arranged for cases which may be either contagious or offensive. In this building each patient is in a room by himself, and all these rooms open into a corridor through which the wind is always blowing. There are many details about this isolating ward which are worth looking at, but which I have not time now to refer to, and I must omit details about the pay ward, the octagon ward, and the peculiar fittings and conveniences of the kitchen, laundry, apothecaries' building, etc., for the same reason.

Let us pass now to the second object of the hospital, the giving means for higher medical education, and see what has been done for that. In the first place, there is a large amphitheatre with appended rooms for the reception of accidents and emergencies of all kinds. In the second place, provision is made for at least thirty students to reside constantly in the hospital, and devote themselves under proper guidance to the study of disease and the practical care of the sick. It is intended that these places shall be open only to those who have had a thorough previous training, and who have shown themselves to be fitted to undertake this important part of their studies. As a rule, not more than five per cent. of medical graduates have had any opportunities worth speaking of to study and treat diseases in the living man when they receive their diplomas. They have to get this experience on their first patients, and sometimes the experience is rather hard—for both doctor and patient. This hospital has provided for the class of the medical school in the last year of their studies good rooms with bath-rooms, a dining-room, and other conveniences, and here they can be taught the actual daily work of a physician, for which all their previous studies are only preparatory. Many of the arrangements of the hospital have been made with reference to this instruction; it is a great laboratory for teaching the practical applications of the laws of hygiene to heating, ventilation, house-drainage, and other sanitary matters. All pipes and traps are either exposed to view or can be seen by merely opening a door, and in the tunnel beneath the corridor you can study at your leisure the complicated and yet simple arrangement of pipes for gas, steam, water, sewage, etc., which are usually buried and remain a profound mystery to everyone except the plumber, and often puzzle even him.

Closely connected with this subject of teaching is that of increasing our knowledge of the causes, symptoms, results, and treatment of disease; in fact, one cannot be thoroughly and well done without the other, and hence many of the provisions for the one are also useful for the other. For example, to go back to our system of heating and ventilation, there are many points connected with it which are destined for experimental work, to compare steam with hot-water heating, to determine the velocity of water at different temperatures, to compare ventilation by aspiration with that by propulsion, or by upward currents with those drawn downward.

One structure is very largely devoted to and fitted for experimental research, and that is the pathological laboratory, where the causes, processes, and results of disease are to be studied. Upon the results obtained in that laboratory may yet depend the saving of many lives, the relief of unspeakable agony, the warding off of pestilence from the city, and, to put it in a strictly business light, the value of real estate and the rate of taxation of this community. We are on the verge of great advances in our knowledge of the causes and methods of disease, and I feel sure that these will be only preliminary steps to far greater and better knowledge of how to prevent or to treat them than we now have. The probable length of life of the new-born infant to-day is not much more than half what it ought to be; the practical productive period of the life of our men and women is shortened and interrupted by unnecessary disease and suffering; but remember, if these things are to be amended, it is not merely by teaching old doctrines; we must open fresh windows and let in more light, so that we can see what these obstacles really are. It is in this work of discovery that it is hoped that this hospital will join hands with the university, and it is in this hope that some of the structures around you have been planned and provided.

A word now on the fourth object kept in view in this hospital, viz., the Training School for Nurses.

Some of you probably have had some personal experience of the difference between an educated, properly trained female nurse, and one of the old-fashioned sort, but if you have not, it would take much more time than I now have to describe it. I can only say, that in many cases a competent trained nurse is as important to the success of treatment as a competent doctor, and that one of the greatest difficulties in treating well-to-do patients in their own homes in this city is the want of proper nurses. Affection and zeal may do much, but they cannot take the place of knowledge, and this kind of knowledge is not to be acquired in a day or in a month. It is a work best carried out by women, though not one woman in ten is fit for it, or should undertake it. But the woman who is fit for it, who has physical health and strength, sound sense, loving kindness, patience and tact, and who has been thoroughly taught the art of nursing the sick, with all its thousand details, has the power of doing good and increasing happiness to a degree which few others possess. In a properly conducted hospital ward she is a necessity, but her field of usefulness and helpfulness is by no means limited to that. She is needed outside the hospital, in the home of the rich, to nurse and care for the sick; in the home of the poor, to teach prevention as well as nursing. To gather here such women, to have them thoroughly instructed, to furnish them with the attractive and comfortable home which they deserve, and to send them where they are most needed, with provision for their return when the work is done, is the object of the training school of this hospital.

For this purpose the trustees have provided a large and handsome building, separated from the others, and exclusively appropriated to the female nurses, where each can have her own comfortable room, and where a common parlor, library, dining-room, bath-rooms, and, in short, the arrangements of a first-class hotel are provided for their use. Here also is a training-kitchen and a lecture-room to aid in the work of instruction. The intention is that when the nurse has finished her six or eight hours' tour of duty with the sick, she shall come quite away from the ward and all that pertains to it, and take her rest and recreation in a totally different atmosphere, and special effort has been made to have this home attractive and pleasant.

The fifth object which I mentioned as having been kept in view in the plan and construction of these buildings is the Dispensary. This is a large building on the north front, consisting of a large central waiting-room, surrounded by a number of smaller rooms for the use of the physicians and surgeons who are to examine and prescribe for the patients, and having bath-rooms, and a small apothecaries' establishment for the issue of the medicines ordered. This building is connected with the amphitheatre by a short covered corridor, and is specially arranged with reference to teaching. It, as well as the amphitheatre, is heated by steam instead of hot water, partly because they are not in constant use, and a rapid means of warming is desired, partly for the purpose already referred to, of giving the means of experimental comparison of the two systems. The means of supply of fresh warm air in these two buildings, and of removing the air made impure by exhalations, are somewhat peculiar, and merit examination.

With regard to the architectural design and external appearance of the buildings, and the laying out and ornamentation of the grounds, I can only say that you must see and judge for yourselves whether Mr. Hopkins' wish that they should be an ornament to the city have been

successfully complied with. So far as external ornamentation is concerned, it is confined almost entirely to the large buildings on the west, or Broadway, front, which it was felt should harmonize in style of decoration. These central buildings, consisting of the administration, with the one pay ward on either side, are constructed of pressed brick with ornamentation of a dark blue, fine-grained, hard, and durable stone, known as Cheat River stone, and of moulded terra-cotta of the color of the brick. The external designs for these, as for all the other buildings, were furnished by Messrs. Cabot & Chandler, of Boston, and I think we have good reason to be well satisfied with the results they have produced. The grounds are laid out and planted in accordance with designs furnished by Mr. E. W. Bowditch, of Boston.

As regards construction, I do not hesitate to affirm that these are the best built buildings of their kind in the world. The material is the best, the most skilled and careful workmen were employed, and, above all, the work received the most careful, conscientious, and intelligent supervision as it progresssd. For this supervision we are indebted to Mr. John Marshall in the beginning, and to Mr. William H. Leeke for the remainder and conclusion of the work; and we are also indebted to the latter for many valuable suggestions as to modes and details of finish, which are so important in a hospital. The details of the complicated and extended system of heating, ventilation, and plumbing were designed and the work executed by Messrs. Bartlett, Hayward & Co., of this city. I should like to go on and mention a number of other names of persons who have done good work here, but want of time forbids. I will only say that these buildings embody the counsels and suggestions of many men and women in this country and abroad, but among them all there is no one who, from the very beginning of the conception of the idea of this magnificent gift in the mind of Johns Hopkins down to this present moment, who has had more to do with shaping the results, who has furnished more valuable suggestions, who is more thoroughly acquainted with all that has been done, and why it has been done, who has worked so unselfishly, and who more deserves honor in this connection, than the President of the Board and Chairman of the Building Committee through the whole progress of the work, Mr. Francis T. King.

Briefly and incompletely as I have sketched these salient points of the plans and purposes of this hospital, I hope I have, nevertheless, shown you that it is intended for other purposes beside providing shelter, food, and drugs for the sick. In saying this I have not the least wish to undervalue or disparage those institutions which do make this their main or only object. There is abundant need of their existence and work also; but this institution should not be judged by the rules which apply to them; it cannot be managed after their fashion; if it does not produce results different from theirs, it is a failure and the expenditure upon it a mistake.

Thus far I have been speaking of the buildings only, and trying to give you some idea of the motives which led to their being as they are, and what they are, and not otherwise. From the beginning, however, it has been recognized that the buildings and machinery are only means to an end, tools which must be handled by skilled workmen to produce the desired results; and throughout all these years of planning and building, the question of organization and of the sort of men and women who were to use and work with these things have not been lost sight of. It is true that no attempts were made to select and engage individual members of the hospital staff until quite recently; but there was, nevertheless, a tolerably definite conception as to the ideas, mode of work, character, and wants of those who are to constitute this staff, and when the time came for selecting, it was made by this standard.

On the philanthropic, social, and religious aspects of this great trust I do not propose to touch, but I wish to say a very few words of the hopes and wishes of scientific men and physicians with regard to it. From the time of the first announcement of the Hopkins bequests to the present, these men, all over the world, have been keenly interested in the plans and methods adopted in carrying them out. Whenever and wherever the problems of higher medical education have been discussed within the last ten years, there has been speculation as to the probable course of the Johns Hopkins medical department, and the influence it would have upon the standard. I may even say that some of this influence has been exerted in advance, has been discounted, as it were, for the plans of this hospital have stimulated changes in some of our best medical schools, and have been copied with more or less modification in some of our latest hospitals.

What is it, then, that the physicians want? Is it more physicians, more family practitioners, more surgeons, more specialists? Not at all. They know very well that there is no danger that the supply will not be equal to the demand; when they become overburdened with practice they do not at present find it difficult to obtain assistants; they have no fear lest the seventy or eighty medical schools of this country should fail to produce a sufficient number of medical practitioners to meet the wants of our increasing population; and they know also that medical schools of Great Britain and Germany are sending to us quite as much of their product as we can conveniently dispose of. They hope that the Hopkins medical school and hospital will do two things. The first is, that it will demand of those who propose to become its students evidence that they have a sound basis of preliminary education before they commence, and that its standard in this respect shall be little below that of the requirements for granting the degree of bachelor of arts in the University. It is hoped that the men thus selected will go through a carefully graded course of study, including actual work in properly fitted laboratories, and that after this they will be brought into contact with the sick, and thus obtain practical experience of the duties and responsibilites of the practitioner of medicine before they offer their services as such to the public.

So much our physicians desire of every medical school, for the sake of the honor and dignity of the profession, and for the good of the public, and they desire especially that this school shall form an example to which they can point as showing how medical education should be conducted, and what should be required of the candidate for the degree of doctor of medicine.

The very general interest in the combined Hopkins trusts felt by physicians and scientific men, not only of this country but of the whole civilized world, is largely due to the belief that the relations which will here exist and be maintained between the University as a whole and its medical department, of which this hospital is to be an important part, will be close and intimate, so that the true University spirit will pervade, stimulate, and encourage the hospital work. In this country medical schools have either had no connection with universities properly so called, or the connection has been slight and nominal, such as depends upon the formal conferring of medical degrees by the University. Here, however, through the influence of the biological department, there are secured common interests and mutual influence, and it is hoped, therefore, that the necessary details of technological instruction will be arranged in accordance with, and subordinate to, the broad principles of scientific culture upon which this University is organized.

It is because it is believed that this will be the case that there is a widespread hope and expectation that these combined institutions will endeavor to produce investigators as well as practitioners, to give to the world men who can not only sail by the old charts, but who can make new and better ones for the use of others. This can only be done where the professors and teachers are

themselves seeking to increase knowledge, and doing this for the sake of the knowledge itself; and hence it is supposed that from this hospital will issue papers and reports giving accounts of advances in, and of new methods of acquiring, knowledge, obtained in its wards and laboratories, and that thus all scientific men and all physicians shall share in the benefits of the work actually done within these walls. But, however interesting and valuable this work may be in itself, it is of secondary importance to the future of science and medicine, and to the world at large, in comparison with the production of trained investigators, full of enthusiasm, and imbued with the spirit of scientific research, who will spread the influence of such training far and wide. It is to young men thus fitted for the work that we look for the solution of some of the myriad problems which now confront the biologist and the physician.

Do I seem to ask too much? to be too sanguine as to what human thought, and study, and skill may accomplish? to forget that there is one event unto all; that the shadow of pain and death comes on the wise man as on the fool? I have two answers. As surely as our improved methods of prevention and treatment, based on the advances in knowledge of the last fifty years, have already extended the average duration of life in civilized countries nearly five years, have prolonged thousands of useful and productive lives, and have done away with the indescribable agonies of the preanæsthetic period, so surely we are on the verge of still greater advances, especially in the prevention of infectious and contagious disease, in the resources of surgery against deformities and morbid growths, and in the mitigation of suffering due to causes which cannot be wholly removed. But the second answer is more important, and it is this: It is our duty to try to increase and diffuse knowledge according to the means and opportunities which we have, and not to rest idle because we cannot certainly foresee that we shall reap where we have strewn. "It is not incumbent on thee to finish the work, but thou must not therefore depart from it," says the Talmud, and "Of him to whom much is given much shall be required," says the Scripture.

To you, the officers of this institution, and to you, men and women of Baltimore, there is now given the opportunity of giving powerful aid in this increase and diffusion of knowledge of the laws of human life, disease, and death. Surely, those who are working in the wards and laboratories of the hospital and University will do their best; surely, also, the citizens of this great city of a great nation, which at no distant day will take the lead in scientific work, will encourage, sustain, and sympathize with these workers. I would have this hospital become famous, not for fame's sake, but because this will be evidence of the good work which has been done in it. But we must not be impatient. There are difficulties to be overcome, delays which must be submitted to. We cannot at once have the medical school which is essential to the plan which I have sketched; but there is plenty to do for the present, and I am certain that in time all these present obstacles to full development will be happily overcome.

Success in this, as in all other enterprises in this world, is to be obtained by unselfish work for the good of others, by wise counsel, by co-operation, and by persistent effort.

A hospital is a living organism, made up of many different parts, having different functions, but all these must be in due proportion and relation to each other, and to the environment, to produce the desired general results. The stream of life which runs through it is incessantly changing; patients and nurses and doctors come and go; to-day it has to deal with the results of an epidemic, to-morrow with those of an explosion or a fire; the reputation of its physicians or surgeons attracts those suffering from a particular form of disease, and as the one changes so do the others. Its work is never done; its equipment is never complete; it is always in need of new means of diagnosis, of new instruments and medicines; it is to try all things and hold fast to that which is good.

"Et quoniam variant morbi, variabimus artes."

It has been said that "hospitals are in some sort the measure of the civilization of a people, but a hospital of this kind should be more than an index. It should be an active force in the community in which it is placed. When the mediæval priest established in each great city in France a Hôtel Dieu, a place for God's hospitality, it was in the interests of charity as he understood it, including both the helping of the sick poor and the affording to those who were neither sick nor poor an opportunity and a stimulus to help their fellow-men; and doubtless the cause of humanity and religion was advanced more by the effect on the givers than on the receivers. It is the old lesson so often expounded, apparently so simple and yet so hard to learn, that true happiness lies in helping others; that it is more blessed to give than to receive.

In some respects we of to-day have a much wider outlook than the men of a thousand years ago. This hospital is designed, as I have told you, to advance medical science as well as to give relief to the sick poor, but the fundamental motive is the same—to help others.

We have here the beginning of an institution which shall endure long after the speakers and the audience of to-day shall have finished their life-work and have passed away. Founded in the interests of suffering humanity, intimately connected with a great university, amply provided with what is at present known to be essential to its work, we have every reason to predict for it a long and prosperous career, with steadily progressing improvement in its organization and methods, and enlargement of its activity and influence.

Let us hope that before the last sands have run out from beneath the feet of the years of the nineteenth century it will have become a model of its kind, and that upon the centennial of its anniversary it will be a hospital which shall still compare favorably, not only in structure and arrangement, but also in results achieved, with any other institution of like character in existence.

Dislocation of the Eyeball.—A singular case of dislocation of the eyeball is related by Dr. Van Dooremaal in the *Dunders Fest Bundel*. A butcher's assistant, in passing out of the shop, caught his upper eyelid on one of the hooks. He begged his fellow-shopman to extricate it for him, but the latter performed his task so awkwarkly that the hook pushed the eye forward, and allowed both upper and under eyelid to disappear completely behind it; even the eyelashes were invisible. The man was brought to Dr. Van Dooremaal. The eye was pushed frightfully forward. The man shrieked incessantly, "Oh, how strong the light is;" and on being asked whether he was in pain, replied: "Yes, but oh, that light, that light!" while he clasped his hands convulsively over his eyes Dr. Van Dooremaal decided to enlarge the external angle of the eyelids by means of blunt-pointed scissors, which were introduced between the protruding eyeball and the outer angle. After the cut had been made, a strabismus hook was introduced along the under edge of the upper eyelid. As soon as the hook had been pushed somewhat inward under the upper eyelid, a curette was inserted, and then pressed outwardly without exerting pressure on the eyeball, so as to bring the upper lid out. This was accomplished without difficulty, and then the under lid was gently drawn back to its place by the thumb. The wound was sewn up as usual, and the eyes bandaged. The wound healed quickly; the reaction was extremely small, but the patient complained of excess of light on the removal of the bandage. The discomfort, however, soon disappeared, and the sight was normal. —*British Medical Journal.*

THE SIGNIFICANCE OF THE CREPITANT RÂLE.[1]

By FRANK W. JACKSON, M.D.,

CHIEF OF VANDERBILT CLINIC, MEDICAL DIVISION; ATTENDING PHYSICIAN TO OUT-PATIENT DEPARTMENT, ROOSEVELT HOSPITAL, NEW YORK.

In "A Manual of Auscultation and Percussion," by the late Dr. Austin Flint, fourth edition, 1885, we find this statement:

"The crepitant râle is the diagnostic sign of pneumonia. It very rarely occurs in any other pathological connection. Of all respiratory signs this is most entitled to be called pathognomonic. . . . The practical value of this sign relates chiefly to the diagnosis of pneumonia" (page 133).

To this theory, which is held by many, I venture to take exception, and it is in the hope of provoking discussion to-night that I bring this subject forward.

My position is, that the crepitant râle alone is *not* diagnostic of pneumonia; that it is simply a sign of inflammation involving the pleura, and possibly of several abnormal conditions of the lungs as well.

A certain degree of difference is to be noted in the definition of the crepitant râle by various writers, but all practically follow the teachings of Laennec or Walshe. Laennec[2] describes this râle under the title of "La râle humide, ou Crépitation." He says: "The moist crepitant râle is a sound which evidently occurs in the pulmonary tissue. One may compare it to that made by salt when caused to decrepitate in a vessel over a gentle fire, or to that given out by a dried bladder when blown into, or, better still, to that given forth by the tissue of a healthy lung distended with air when one presses it between the fingers. Only it is a little louder than this last, and beyond the crepitation it carries with it a well-marked sensation of moisture. One plainly perceives that the pulmonary vesicles contain a liquid almost as thin as water, and which does not prevent the air from entering. The bubbles which it forms appear extremely minute."

Here it will be noted that the râle is spoken of as *moist*.

Walshe[3] calls it "a crepitating (or crepitant) rhonchus," which, he says, "when developed in perfection occurs in puffs more or less prolonged, but rapidly evolved, composed of a variable, sometimes immense, number of sharp, crackling sounds, all perfectly similar to each other; conveying the notion of minute size; dry; co-existing exclusively, except in rare cases, with inspiration, and, once established, remaining a persistent condition until superseded by other phenomena. . . . Dryness is one of the best-marked acoustic properties of true crepitation. The sensation is not that of bubbles bursting, but rather that of a delicate tissue undergoing minutest ruptures with a crackling noise at many points simultaneously. . . . When at its maximum, crepitant rhonchus accompanies almost the entire act of inspiration; when first developed, and also when about to be superseded by blowing respiration, it appears toward the close of inspiration only. Under all circumstances it is, to say the least, rare to find this rhonchus co-existent in any degree with expiration."

It will thus be noted that in an acoustic property attributed to this râle these two authorities differ very widely; the one dwelling upon the element of moisture, the other on the extreme dryness of the sound. It has seemed to me that, as usual, both are right. That taking the crepitant râle, even as heard in pneumonia, the sound may at one time be quite moist and again quite dry. Such a variation I have noted occasionally in the same case of pneumonia on different examinations, and frequently in cases of dry pleurisy. If the seat of the crepitant râle in these cases be attributed to the pleura, the explanation of the varying degree of moisture or dryness of the sound is to be found in the varying amount of serum contained in the fibrin on the pleura or in the meshes of the adhesions. It also seems to me that there is another important variation in the character of the sound, viz., in the degree of *fineness* of the râle; some râles are much coarser and of more volume than others, although still a fine râle and heard only on inspiration.

As regards the mechanism of the crepitant râle there are now three leading theories which are offered in explanation of the sound:

That of Laennec, that it is due to the bursting of fine bubbles of air through a viscid fluid in the air-vesicles or alveolar passages of the lungs.

That favored by Walshe, that it is due to forcible distention of air-vesicles, whose walls are rendered stiff, or are "starched," by a glutinous exudation.

Finally, the theory so ardently advocated by Dr. James R. Leaming, that the crepitant râle is not produced in the lung, but by the rubbing together of the two surfaces of an inflamed pleura which are coated with fibrin, or by the stretching of adhesions of the pleuræ.

In order to gain some idea as to the general sentiment of writers in regard to the significance of this râle, I have hastily consulted a few of the acknowledged authorities upon this subject. The general result of such investigation is, that all writers, up to a few years ago, believed the crepitant râle to be pathognomonic of lobar pneumonia in its first stage. That among recent writers most of those in Germany and France favor the intrapulmonary origin of the râle, and consider it a valuable sign in the diagnosis of pneumonia; but, at the same time, ascribe the râle to other pathological conditions of the lung as well; and that while most of the English writers follow the teachings of their German brethren, the fact that pleural changes will produce a crepitant râle is recognized by several; while in this city, at least, many of the more recent writers and teachers ascribe the râle to pleuritic exudation. Nearly all modern writers agree, however, that the crepitant râle is *not* pathognomonic of pneumonia.

Thus Guttmann[1] states that the proper diagnostic inference from the crepitant râle is simply that the alveoli contain both air and fluid, and that this condition occurs in the most pronounced form in the first and third stages of pneumonia. He thinks that the conditions are also present in œdema of the lung, for the production of the râle; but there being fluid in the bronchi as well, a coarser râle is added. Eichhorst[2] makes the same statement, except as regards œdema of the lung, in which he considers that a crepitant râle is heard.

Juergensen,[3] while regarding the râle as a valuable sign in pneumonia, denies that it is pathognomonic. He states that it is also heard in beginning œdema of the lung; in collapse of some air-vesicles at the bases of the lung after prolonged decubitus, and sometimes, though rarely, in cases of "pleuritic exudation unaccompanied by pneumonia."

Germain Sée[4] regards the crepitant râle as the characteristic sign of inflammatory engorgement of the lung, and also draws attention to the fact that sometimes the râle is not heard until the respiration has become bronchial, *i.e.*, the stage of consolidation. He does not attempt to explain the mechanism of the râle in this latter condition of the lung, which can neither be due to the distention of the already over-distended air-vesicles, nor to the passage of bubbles of air through tissue now impervious to air. He, perhaps unconsciously, indicates the explanation, however, a little further on, when he directs us to search carefully

for the crepitation "first at the level of the seat of pain." This pain we know to be caused by the inflamed pleura.

In "Quain's Dictionary of Medicine,"[1] 1884, it is stated that there are at least four conditions which will give rise to the crepitant râle; namely, incipient pneumonic consolidation, œdema of the lungs when not excessive, mere temporary collapse of some air-vesicles, and certain cases of œdema of the pleura dependent upon old lung disease.

W. Douglas Powell[2] says: "The fine crepitation of pneumonia is exactly imitated by other conditions: pulmonary collapse from disease, certain degrees of pulmonary œdema, œdematous pleura, and the first stage of pulmonary apoplexy may be instanced as several circumstances in which the sound may be produced." He thinks that the application of the term "dry" to the sound, while acoustically correct, is peculiarly misleading, for moisture of tissue is probably one of the conditions essential to its production. "Thus, the sound may be most typically heard over a pleura, the two layers of which are separated by œdematous cellular tissue, a condition commonly found over old contractile lung consolidations."

Samson Gemmell[3] holds practically the same views as the above. He says, "certain forms of pleuritic friction often closely resemble it" (the crepitant râle).

Sir Andrew Clark,[4] in his admirable series of lectures, on "Some Points in the Natural History of Primitive Dry Pleurisies," distinctly refers the fine râles which he hears to changes in the pleura and not in the lung, and verifies his statements with autopsies. It is but fair to state, however, that he does not mention whether these râles are crepitant or subcrepitant.

Turning now to writers and teachers in our own country, we find that for a number of years Dr. Leaming has been untiring in his advocacy of the, till then novel, doctrine of the interpleural origin of râles. At first his teachings met with a storm of opposition, but many of his arguments are so good, and many of his cases with autopsies so convincing, that little by little his views have been accepted, in part at least, by a large number of the profession. I say in part, for I doubt if there be many who dare accompany him the whole way, and regard all fine râles as having their seat in the pleura alone. It is particularly the crepitant râle which is accepted as having its origin in the pleura, and it is that alone which concerns us to-night.

Dr. Leaming bases his argument for the pleuritic origin of the râle in pneumonia, apart from theoretical considerations, which we will not discuss here, on the presence of fibrin on the pleura in these cases, and the very significant fact that râles were heard shortly before death when the lung was found to be completely consolidated upon autopsy. Here it is obvious that no air could enter the air-vesicles to distend them, or to produce bubbles in a viscid fluid. He says:[5] "More extended experience has proved to me that the seat of crepitant râle is almost always interpleural. . . . Centric pneumonia, without interpleural plastic exudation, is unaccompanied with râles, either crepitant or subcrepitant, nor is there bronchial breathing. And, again, crepitant râles may exist without pneumonia, as when interpleural adhesions are very close, and do not allow of but slight movement of the lung almost at the end of forced respiration, when there will a little shower of crepitant râle."[6]

He believes the râle to be "a valuable sign of pneumonia or of phthisis, as it often accompanies these diseases; but it is not pathognomonic. It may exist in the absence of both, and either may be present without crepitant râles." He denies that this râle is heard in œdema of the lung.[7]

The views of the late Dr. Flint have already been mentioned.

Dr. Loomis states[1] that as soon as the congestion is well marked in pneumonia crepitant râles are heard, "which have been regarded as characteristic of the first stage, but which are usually pleuritic crepitation." He regards the râle of œdema of the lung as a subcrepitant râle.[2]

Dr. Delafield teaches that the crepitant râle is heard in pneumonia, in phthisis, and in dry pleurisy, and that it is probably a pleuritic-friction sound. Differing somewhat from other writers, he teaches that the stage of congestion in pneumonia may give a *sub*-crepitant râle and a crepitant râle, if there be pleurisy early, and that the crepitant râle may persist in the stages of complete hepatization, if the lung move enough. Of course the râle may be heard during the stage of resolution.

Dr. Roosevelt[3] attributes the crepitant râle to the three possible causes before mentioned, and regards the rubbing together of inflamed pleural surfaces as the most common cause; he thinks it "not unlikely that this is really the only cause." It is heard in pneumonia, in broncho-pneumonia, in pleurisy, and in phthisis.

Dr. S. S. Burt[4] thinks that this râle probably originates in the pleura.

In relating my own experience and opinions in regard to the crepitant râle, I am only too well aware of how little I have to offer in scientific corroboration of my statements. The exact study of the phenomena of râles demands that the râle shall have been heard at the shortest possible period before death, its position on the chest-wall carefully marked, and its acoustic characters equally carefully noted, and then that the lungs and pleura be subjected to a careful post-mortem examination with reference to these data. Thus far I have been able to conform to these requirements in but a few instances, and, consequently, I have not yet acquired sufficient statistics to be of any real value. In the work so far done I have been greatly assisted by Dr. Roosevelt, the assistant pathologist of Roosevelt Hospital, who has kindly examined the pleuræ of such cases for me. In general terms it may be said, however, that where a fine râle was heard on inspiration, some pleural changes were commonly noted at or near the site of the râle, but not always of such a character as to be convincing.

From a strictly clinical stand-point, however, I have studied the phenomena of crepitant and subcrepitant râles for several years with considerable care, and it is from this stand-point alone that I venture to speak with any degree of confidence. As a result of such experience I would note some exceptions to the general statements in regard to the crepitant râle.

The râle is not always persistent when once established. Frequently it has been plainly heard, and a few moments later found to be entirely absent, only to return in a few moments again. This phenomenon has often been observed by other physicians examining cases with me, and by my students. It is my experience that the extremely fine, extremely dry sound, occurring in a great number of crackles, is a rare form of the crepitant râle, whether associated with pneumonia or any other pathological condition. The extremely dry and extremely fine râle is heard commonly enough, but it does not occur in a shower of crackles; there are heard, perhaps, from six to twelve crackling sounds over a given area, and usually these sounds are not very loud, and sometimes they require the most careful examination to recognize them. They have been most frequently heard in cases of old dry pleurisy, or late in the stages of consolidation in pneumonia. Of the brilliant, explosive, abundantly crackling type of crepitant râle, that which is slightly moist and a trifle more coarse in quality seems to me to be far more com-

mon. Such a râle I have frequently observed in three conditions, viz., in acute lobar pneumonia, in acute dry pleurisy, and in phthisis. Much less frequently I have observed it in broncho-pneumonia. In not one of the above conditions could it be told, by the râle alone, whether one had to do with a case of pneumonia or not. It may be mentioned, as an example, that for several weeks I was in the habit of showing to my students a man, who was a regular attendant at the hospital out-patient department, as a case with a typical crepitant râle. Yet at no time did he have a temperature of more than 100° F., he had but slight cough, and no bronchial voice or breathing. He did not look nor feel seriously ill, and his only complaint was pain. The diagnosis was acute dry pleurisy. I have met with many cases of unmistakable phthisis in which the crepitant râle was heard as distinctly as in pneumonia. I have been struck with the number of patients who apply for treatment whose chief, sometimes sole, complaint has been of pain in the chest, and in whom careful examination reveals the physical signs of a little dulness, and a variable number of fine râles, either of the crepitant or subcrepitant variety, at the seat of pain. These sounds are superficial, are confined to a small area (usually), are increased by cough and deep inspiration, and are found most commonly in the following regions, in the order named: the right anterior base, either axillary region, the left anterior base, either posterior base, the rest of the lung. So common is it to find this condition, which I regard as due to recent or old fibrin on the pleura, or to adhesions, that the diagnosis of intercostal neuralgia or muscular rheumatism is rarely entered in my case-book. Râles at the apices of the lung, if old pleurisy be excluded, are commonly found to indicate phthisis, although the râles are referred to a localized pleurisy.

It may be urged that these sounds are not crepitant râles, but yet in everything but the element of a "shower of crackles" they correspond to the definition. They are certainly very fine râles, heard only on inspiration.

I have seen cases of pneumonia without râles until the stage of resolution is reached, and I have heard the crepitant râle over areas of marked dulness and bronchial voice and breathing, though in this case the râles have been much fainter and fewer in number than they usually are earlier in the disease.

I have always regarded the râle of œdema of the lungs as a *subcrepitant* râle of a peculiarly liquid quality.

I have always felt sceptical, to say the least, in regard to the crepitant râle being heard after prolonged decubitus and the like.

The conclusions to be drawn, then, from the study of this subject are: 1, that the crepitant râle is not pathognomonic of pneumonia; 2, that it is heard also in dry pleurisy, in phthisis, and in broncho-pneumonia 3, that there is a strong probability that the râle is always due to pleuritic inflammation; 4, that the question as to its being heard in œdema of the lung and pulmonary apoplexy is yet unsettled.

Dr. Josiah Hasbrouck died in Rondout a short time ago of heart disease, aged fifty-nine years. He began the practice of medicine in 1856, and was President of the Ulster County Medical Society in 1875. He was also a director of the State of New York Bank for many years. Mr. Hasbrouck took considerable interest in politics. He served three terms as supervisor and was elected coroner twice.

An Editor's Opinion of the Medical Profession.—The *New England Medical Monthly*, referring to the recent foolish action of the London College of Physicians and Surgeons, says: "'There is an old adage that 'There is no fool like the old fool,' but we believe that there are no people or profession in the world that make such fools of themselves as do doctors, either alone, individually, or collectively as societies."

SIMULO AS A REMEDY IN EPILEPSY.[1]

By M. ALLEN STARR, M.D., Ph.D.,

CLINICAL PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

In March, 1888, Dr. W. Hale White, of London, published in the *Lancet* some observations upon the use of simulo in the treatment of epilepsy. The drug was used in the form of a tincture, in one to two drachm doses three times a day. This tincture was made from the seed of the simulo plant (*capparis corriacea*). The fruit of this plant resembles a cherry, and is about half an inch in length. The skin is tough and brown, the body is softer and green, and surrounds an almond-shaped pit with white kernel. The kernel has a bitter taste, and it is from it that the tincture is made. The tincture itself is of a yellowish-brown color, and has an aromatic taste, reminding one slightly of sherry.

Dr. White[2] reported seven cases of epilepsy treated by simulo, all of them being cases in which several fits occurred every week.

In the first case neither simulo nor bromide was of any particular benefit. In the other cases there was considerable improvement while taking simulo, the dose being from one-half to two drachms, t. i. d. The attacks diminished in frequency and were less severe while the patients took the drug.

In Case II. the improvement was temporary. In Case III. the fits were reduced from sixteen per week to four per week. In Case IV. the fits were reduced from twelve per month to three per month. In Case V. the fits were reduced from one or two daily to two per month. In Case VI. the fits were reduced from one a month to none in two months. In Case VII., a case of unilateral spasm, with paresis, the spasm was very much relieved while taking the drug, though it had not been affected by large doses of bromides.

Dr. White concludes by stating that he would not have it thought that simulo will cure epilepsy. He believes that an improvement occurs while taking it, and that it may be used as a substitute for bromides when these produce ill effects.

In August, 1888, Eulenberg, of Berlin, published some observations made after using the drug for a few months on seven patients—four epileptic and three hysterical. It appeared to have no effect whatever in the cases of hysteria—the attacks of hysterical or hystero-epileptic character persisting in spite of its use.

In three of the four cases of epilepsy its effect was found to be weaker and less certain than moderate doses (90–120 grs. daily) of bromides. In the fourth case, in which the use of bromides for years had not succeeded in reducing the number of attacks below four to eight in a week, the effect of maximum doses of simulo (3 vj. daily) was to reduce the number of attacks to two to five in a week. Subsequently this patient was put upon simulo and bromides for fourteen days each alternately; and it was found that during the two weeks when he was taking simulo the attacks were less frequent than during the two weeks when he was taking bromides; at the same time he felt much brighter and better while free from the effects of bromide. Subsequently Eulenberg combined the bromide with the simulo, giving a half-dose of each, and the effect was at first as favorable as under the use of larger doses of simulo alone. The favorable effect, however, did not last; the number of attacks gradually increased, and the intervals between them became shorter. Finally the patient was put back upon bromides alone.

Eulenberg concludes that while simulo is not without use, it is decidedly inferior to bromide in its effects.

Having seen the article in the *Lancet*, in April, 1888, I requested Mr. Fraser, of 208 Fifth Avenue, to import some tincture simulo from Christy & Co., in London, the man-

[1] Read before the Section in Practice, Academy of Medicine.
[2] Lancet, March 31, 1888.

ufacturers. This he did during the summer, and I began its use in October last. The following cases were selected from a considerable number of epileptics under observation, as they were cases of extreme severity, and seemed to offer the conditions for a fair test of the powers of the drug. In mild cases, where attacks are occurring but once in one or two months, there are so many factors to be considered in the causation of individual attacks as to make any conclusions regarding the action of remedies somewhat unreliable. Intercurrent indigestion, mental excitement, etc., play a great part in inducing these occasional attacks. But when several attacks are taking place daily the power of a drug to avert attacks can be tested with some certainty.

The results reached have been of interest to me, and may be of profit to others. Therefore I have ventured to lay them before you now.

CASE I.—M. H——, aged forty-eight, has had hysteria and epilepsy since age of sixteen; attacks of grand mal about once in two months, and attacks of petit mal about four to six daily. She has been under my observation continuously since December, 1887, and the effects of treatment have been carefully noted. She has been upon bromides much of the time, since these have the effect of reducing the number of the petit mal attacks to one or two daily, and of decidedly reducing the grand mal attacks in frequency and severity. But the effect of bromide in this case is to produce a condition of very extreme nervousness, with constant sense of fear, great depression with sleeplessness, and suicidal tendency and polyuria. She becomes extremely hysterical as soon as the dose is pushed beyond forty grains daily—is in a state of constant tremor and alarm. For this reason it has been impossible to keep up bromides continuously. This effect is not from any dread of the drug, as I have often given it without her knowledge, producing the same effects, and the addition of caffeine, digitalis, belladonna, or atropia to the bromide does not obviate this effect. The case has, therefore, been very difficult to manage, and very little success has been obtained. Nitroglycerine has always controlled the petit mal attacks better than any other drug, but has no effect upon the grand mal attacks. Antipyrin and antifebrin have been tried and proved useless in this case.

In October last she was put upon tincture simulo and kept upon it for two months. The frequency of the petit mal attacks was in no way affected; they became more frequent than when she was using either bromides or nitroglycerine. But during this period of two months she had no severe convulsions. She was an extremely hysterical patient and at times her attacks were doubtless of a hysterical character. The drug did not appear to mitigate the hysterical symptoms in any way, and, as the petit mal attacks increased, it was thought best to suspend the treatment.

In this case it failed to arrest hysterical attacks or attacks of petit mal, but for a time prevented the occurrence of grand mal attacks.

CASE II.—L. G——, aged twelve years, has had epilepsy ever since she was a baby, her attacks consisting of slight convulsions, with loss of consciousness and loss of urine. She came under treatment October 20, 1888, and was at that time having attacks every day or two. She had taken bromides without any very marked effect. She was put upon tr. simulo, in ʒ ss. dose t. i. d., which dose was increased to ʒ ij. t. i. d. During the first week she had 5 attacks; second, 3; third, 2; fourth, 2; fifth, 2, but one severe; sixth, 3, but one severe. She then remained away for four weeks, keeping up her medicine, and on reporting on January 12th said she had had six attacks since January 1st. The effect of the simulo was therefore to reduce the number of attacks from about five a week to about two or three a week, and to diminish their severity, as in the attacks she no longer lost control of the bladder.

CASE III.—L. M——, aged sixteen. Grand mal attacks, occurring chiefly at night, since age of fourteen, at first irregularly, then more frequently, one every four or five days. During December, 1888, she had three attacks every night for three weeks, followed by an intermission of eleven days without attacks. In addition to grand mal attacks, with biting of tongue, falling, and sleep, patient has petit mal attacks, consisting of either a sensation of fainting, with pallor, or a slight twitching of her face and hands, with very short loss of consciousness. These occur several times daily. She was put upon tr. simulo, ʒ iij., on January 8th, which was increased to ʒ vj. on January 29th, at which dose it was kept up until February 26th. She had no night attacks from January 8th to 19th, and no fits of grand mal until February 1st, when she had one, but between February 17th to 20th she had four grand mal attacks, two in the daytime.

During the month of February she had seventy-five attacks of petit mal, no day passing without one, and on some days four occurred. The simulo evidently had no effect upon the petit mal attacks, but diminished the grand mal attacks very much—from sixty-three attacks in December to five attacks in February. During the month of March, on bromide, chloral, and belladonna, with nitroglycerine, she had no grand mal attacks and but eighteen petit mal attacks.

CASE IV.—F. S——, aged fifteen. Grand mal attacks, preceded by aura of sudden speechlessness, with turning of head to the right, attended by cry, loss of consciousness, biting of tongue, severe fall, loss of urine, and general convulsion, followed by stupor. These have occurred since age of twelve, when first attack occurred at 6 A. M., without any known or ascertainable cause. The attacks recur about every three weeks, in spite of bromide treatment. General health very good and appearance healthy. Had been under bromide treatment until February 4, 1889, when tr. simulo, ʒ iij. daily, was begun. Attack on February 16th. On February 23d, tr. simulo, ʒ v. daily, and up to April 16th no attacks had occurred, an interval of eight weeks instead of the usual interval of three weeks.

CASE V.—John H——, aged eighteen, had convulsions as a baby, but was free from them until the age of fifteen, when he had an attack of grand mal. Such attacks have recurred at shorter and shorter intervals, and when he applied at the clinic, January 31, 1889, he had had one attack every month for several months. He was put upon simulo, ʒ vj. daily, and reported on March 30th that he had had no attacks since the treatment was begun.

CASE VI.—Max L——, aged twelve, has had epilepsy ever since the age of two years. He has attacks of grand mal about once a month, and attacks of petit mal several daily. He was put upon tr. simulo, ʒ vj. daily, on December 26th, and took it constantly until March 11th. During this time he had no attacks of grand mal, but the attacks of petit mal continued as before.

CASE VII. *Procursive epilepsy.*—W. V——, aged nineteen; patient has had procursive epilepsy since the age of seven, the attacks consisting of a sudden pallor followed by a flushing of the face, and a sudden movement of the body, which he cannot control. In the daytime the movement consists of a sudden running forward for twenty or thirty steps without falling, followed by a laugh or a few incoherent words. This may or may not be attended by a loss of consciousness. He usually avoids objects in his way when running, but is not arrested by anyone calling him. At night in bed the movement consists of a sudden violent turning from side to side rapidly and repeatedly, followed by the same laugh, or a few words, or by the saying of a line of a song. These attacks have never been controlled by bromides. He has from three to six daily, and during the year 1888 his average was 100 every month. These attacks were in no respect changed by the use of tr. simulo; the number of attacks in December, 1888, being 93, and in January, 1889, 126, during which time he was taking simulo in ʒ v.–vj. doses

daily. During February and March he was put upon bromides and nitro-glycerine. The number of attacks in February was 60, a reduction of one-half, but during March he had 115, of which, however, 49 occurred during the last week of the month, coinciding with an attack of indigestion. As bromides alone had always failed to control these attacks, it seems as if the nitro-glycerine was responsible for the diminution in their frequency.

In addition to the procursive attacks this patient has nocturnal convulsions. These convulsions had been noticed at the age of nine, but were immediately controlled by bromides and chloral; and from the age of ten to that of seventeen no convulsions occurred. But for certain reasons the bromides were stopped suddenly in October, 1887, and two weeks subsequently he had a typical attack of grand mal at night, and during the six months following he had 21 such attacks. The bromides were then begun again but no longer prevented the attacks, and during the period from April 15th to October 15th, 26 attacks had occurred in spite of their use. They were then stopped again, no medicine being given until December 10th, when he came under my care. Between October 15th and December 10th he had 43 attacks of grand mal, with all its severe phenomena. It seems evident, therefore, that the results of seven years' continuous treatment with bromides in absolutely controlling the grand mal attacks were obviated by the sudden cessation of this treatment, with the result of establishing an epileptic habit which now refuses to yield to the bromides which previously had prevented its development. It follows that the sudden cessation of the use of bromides is not unattended with risk. This patient was put upon tr. simulo on December 10th, in 3 iv. dose, which was increased to 3 vj. dose. He had 4 attacks between December 10th and December 31st, and 8 attacks during January. It is evident, therefore, that since without medicine he had had between 15 and 28 attacks per month, while with tr. simulo he had 9 and 8 attacks per month, that the remedy had some effect in decreasing the nocturnal convulsions. As, however, on bromides he had had but 3 to 6 attacks per month, I put him upon bromide, chloral, and belladonna on February 1st. During the month of February he had but 3 attacks. During March he had 12, the attack of indigestion being responsible for seven of these, just as it was for an increase in the procursive attacks.

The general conclusions to be drawn from these cases seem to be that:

1. Tr. simulo has no effect upon attacks of hystero-epilepsy or upon the hysterical state.

2. Tr. simulo has no effect in modifying the frequency or severity of attacks of petit mal, or of procursive epilepsy.

3. Tr. simulo has some effect in modifying the frequency and severity of attacks of grand mal, but is inferior in this respect to the bromides.

4. In cases where for any reason it is deemed necessary to suspend the bromides, it would be well to substitute simulo for them.

There seem to be no ill effects from the use of the drug. I found no evidence of change in the rate or character of the pulse or respiration, no dilatation or contraction of the pupils, no muscular weakness, no mental depression or excitement, and no disturbance of the digestion in the doses in which it was used. The suggestion made by Eulenburg, that it would be well to obtain the active principle of the drug, is worthy of consideration. And I think it would be well to increase the dose progressively until one or even two ounces are used daily. The chief objection to its use at present is its costliness, the price being twenty-five cents an ounce.

Several College Presidents write that they had been using the treatment by suspension long before it had been suggested by Motchoukowsky or Charcot.

Progress of Medical Science.

The Waiting Method, or the Method of Credé in Expressing the Placenta.—This is the title of a book on the physiology and management of the third stage of labor, by F. Ahlfeld, Leipsic. The writer explains why he and other authors have abandoned the active method of Credé in the treatment of after-birth. They found it a disturbance of the physiological course of the third stage of labor, which is a source of numerous and unfavorable accidents, as hemorrhage, retention of the membranes, and severe diseases pecuhar to the lying-in period. Ahlfeld prefers the method of Schultze to that of Duncan, it being more normal. The last pain which expels the child also separates the placenta by the decided contraction of the uterus. Then, during the next four or five after-pains, it passes deeper, and after about thirty minutes finds itself in the entrance of the vagina, closely followed by the membranes in a complete state. While the placenta moves deeper the fundus uteri ascends above the height of the umbilicus, and lies to the right under the liver. It usually has the form of a ball, with the walls in close apposition, and a blood-filled cavity is generally not found. The power of the abdominal pressure is very small in the third stage. In from one to two hours after the birth of the child a condition presents which he terms continuous contraction. The loss of blood after the birth of the child in the waiting method averages 453 grains, in four to five hours. In primipara the loss of blood in the first hour and a half reaches on the average 414 grains, in multiparæ 580 grains after delivery. The manner of the separation influences also the amount of blood. The author further delineates the means of the physiological predecessors of the course of the third stage. The retro-placental hemorrhage promotes the descent of the placenta, tampons the placental site, protects it against infection and incites pains. He finds the physiological antecedent of the separation of the placenta in the ampullar strata especially reasonable, the compact strata remaining on the chorion and is not expelled. If the separation does not occur in this manner, which is frequently the case, there remains a deep decidual strata, which decomposes easily, causes hemorrhage, and retards involution of the uterus. Atony of the uterus in normal conditions is not to be feared in the waiting period, also secondary and late hemorrhage are not to be expected. The author next employs himself with the sequence of the method of rapid delivery of the placenta. These consist of tearing of the fetal membranes, retention of the small placental parts, hemorrhage after expression, secondary and late hemorrhage, sub-involution, fever, and light and severe septic disease. These results are less frequent in well conducted institutions, but especially numerous in the practice of midwives. In reviewing his long years of experience, he gives decided preference to the waiting method, which he recommends as the best, surest, and least dangerous. The procedure is thus described: After the birth of the child, the external genitals are cleansed; bleeding, tears, and bruises closed; dry clothing placed under the patient, and this clothing observed every five minutes to tell whether it is bloody, especially whether blood is flowing from the vagina. If this is not the case, as in eighty per cent., the clothing under the patient remains. After sufficient time has elapsed and the bladder is evacuated the placenta is expressed through the vagina by means of mild external pressure; its passage through the vulva should take place as slowly as possible. If a severe hemorrhage occurs during the expression of the placenta the uterus is manipulated until the hemorrhage ceases, then the waiting method is continued. If, however, the hemorrhage is not subdued, the rapid expression of the placenta is found to be necessary. In the waiting method the patient must be as quiet as possible. Cold douches for the purpose of disinfection, and all irritation of the uterus except the massage are to be avoided. The

waiting method is to be recommended in the practice of midwives, and will result in far less damage in their hands than the expression of the placenta.—*The American Lancet.*

DIABETES AND TUMORS.—Dr. Tuffier has recently published a monograph on this subject. The coincidence of diabetes and neoplasms, only noted hitherto in a few scattered publications, and entirely overlooked in standard text-books, does not appear to be rare. This coincidence is not surprising to the author. He accepts M. Verneuil's bold theory that both tumors and diabetes are related to the arthritic diathesis. Already almost every form of tumor has been observed in diabetic patients. Almost every form of diabetes has been found to attack persons already the subjects of tumor. As a rule, the constitutional disease comes first; the patient is diabetic already before the tumor makes it appearance. Malignant tumors, as a rule, advance without causing much pain, and somewhat slowly in these cases, but they proceed more rapidly than the diabetic symptoms. They are apt to be taken for innocent growths. The complication in question is very serious in respect to operative interference, as we all know. No surgeon should think of removing small, innocent tumors which are causing no trouble.

Dr. Tuffier describes two instructive cases. In the first death occurred forty hours after the removal of a small parotid tumor. The fact that the patient was diabetic had been overlooked. This was also the case in the second example of the dangers of operation under the circumstances. "A little hypertrophic tumor of the skin of the cheek" was removed, at the patient's request. Phlegmonous erysipelas, followed by sloughing, set in and killed the patient within five days. Urgent operations must, Dr. Tuffier asserts, be undertaken with great caution. The safer are preferable to the most thorough, in his opinion. When an operation appears absolutely necessary, but not urgent, it is important to spend some time in reducing the diabetic symptoms by medical treatment. Should, however, all the sugar and the polyuria disappear, the surgeon must still never overlook the nature of the patient's diathesis. Under the most favorable circumstances, in any case of that kind, deep operations and prolonged dissections, free division of vessels, and the formation of large flaps are to be avoided. The slow progress of tumors and the little pain which they produce are important facts, according to Dr. Tuffier. He has found that malignant tumors lie almost latent in diabetic subjects for a long period. Removal of a similar growth from a healthy subject would hardly insure him against so long an interval of time before recurrence. When an operation is thought advisable, the thermo-cautery is preferable to the knife. No attempt to insure union by first intention should be made if it involves the slightest traction on skin-flaps. The wound must be laid open, but dressed with extreme antiseptic precautions.—*The British Medical Journal.*

WHAT IS A DISEASED OVARY?—Since the establishment of oöphorectomy as a recognized operation, many pathologists have testified to the hopelessly disorganized conditions of the structures which the surgeon has removed. Tubal disease, once considered a pathological curiosity, has been proved to exist as a common disorder by the researches of Drs. Kingston Fowler and Lewers. Forms of oöphoritis, destructive to the ovary at least, if not also prejudicial to the organism, have been revealed by diligent and unbiassed pathologists. Gynæcologists of the older school mostly admit the result of these discoveries, but maintain that the frequency of signs of chronic ovarian disease in the bodies of subjects who have died of other affections counterindicates radical operations, or indeed any operation at all. The oöphoritis, or salpingitis, detected in these cases clearly failed to kill the patients, and evidence that medical relief was sought is ever defective. The specialists, however, note the hopelessly diseased condition of the ovaries, as corresponding to authentic clinical histories of bad symptoms, definite and objective, as well as subjective. They declare that cases believed to be cured by expectant treatment have applied to them for relief which was afforded them by oöphorectomy. They further imply an imperfectly recognized motive—want of surgical confidence—in their opponents. No honest member of our profession can doubt that the older school are justified in insisting upon a close scrutiny of the results of operations for chronic diseases of the tube and ovary. The great operating specialists freely publish their results; but it is, in the present stage of our knowledge, extremely advisable that the inexperienced should abstain from these operations. Above all, science must throw more light on oöphoritis. Dr. Nagel, of Berlin, has published an article entitled, "Contributions to the Anatomy of Healthy and Diseased Ovaries," based on clinical material, chiefly supplied by Professor Gusserow. Dr. Nagel does not believe in the chronic follicular oöphoritis of certain pathologists. He considers that the condition simply implies an unusual number of follicles in a healthy ovary as an individual peculiarity. The follicles, at least, are normal, however the condition of the stroma may be disputed; and his researches show that morbid changes in the stroma do not affect the follicles for a long time, but ultimately cause their disappearance. They cannot proliferate by any morbid process. Nor does Dr. Nagel lay any stress on "hydrops folliculi." Follicles, half an inch in diameter, he found perfectly healthy, bearing ova. A large follicle, bearing its usual epithelium, but without its ovum, represents a degenerate condition, and cannot develop into a cystic tumor nor take any active part in the development of such a tumor. On the other hand, Dr. Nagel gives reasons why we may conclude that simple cysts of the ovary are generally cystic degenerations of the corpus luteum. Oöphoritis, however, he holds to be essentially interstitial, and he concludes, after examining a series of ovaries, that in all cases, directly an ovary becomes diseased, the interstitial tissue between the follicles, that is to say the stroma, is first attacked. The follicles retain their normal appearance, and continue to bear and nourish healthy ova for a remarkably long period after the onset of oöphoritis. As Slaviansky has already indicated, the follicles begin to wither directly the morbid changes in the stroma have reached a certain limit. The atrophy is in some cases active, in others passive. As a rule, circumscribed peritonitis is the cause of the disease, which progresses from the surface of the ovary inward. Dr. Nagel has, however, detected one case of true acute interstitial oöphoritis as a primary disease. This form leads to Kiwisch and Klob's "hypertrophy with sclerosis," where the ovary can grow as large as a goose's egg, its surface appearing like a mulberry. Dr. Nagel concludes that the later stages of oöphoritis represent an incurable condition, and that operation is justified for the removal of ovaries so affected. The operator must, however, bear in mind his important observations, which tend to prove that every ovary a little fuller than he thinks it should be is not necessarily morbid, and that a cystic projection from the surface of a small ovary is not sufficient evidence that it ought to be removed. The histologist, too, would do well to study the healthy human ovary from its earliest stages of development to its normal condition of atrophy after the menopause, and to teach what he sees to his pupils.—*The British Medical Journal.*

CHOCOLATES, confectionery, dried fruits, cheeses, and other food products are very often wrapped in what appears to be, and is described as, tin foil, but it is really an alloy, containing a good deal of lead. This dangerous practice is now prohibited in France, and the tin foil destined for wrapping food-stuffs and confectionery must be composed of "fine tin," that is, an alloy containing at least 90 per cent. of tin.—*British Medical Journal.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, May 11, 1889.

RUDIMENTARY ORGANS IN MAN.

THERE are two views of the theory of evolution current among medical men. Some, believing that all forms of animal life have developed gradually from one original form, find support for their view in the presence of rudimentary organs in the human body—remnants, they tell us, of organs which, in the development of the human body from an animal body of a lower type, have become useless.

Others, holding that there are great breaks in the course of evolution, and that the human body has not been developed from a lower form, but is a separate creation, view these rudimentary organs not as remnants of a pre-human type, but as essential parts of the human body, which, during the development of the human fœtus, or during extra-uterine life, serve in various ways, which have not yet been discovered, to perfect the adult form.

To those who wait for such discoveries, the brief but suggestive article of Dr. Cane (London *Lancet*, September 29, 1888), entitled "The Mechanism of Fœtal Formation," will be of especial interest. "The puzzle of rudimentary organs," he says, "has occupied my attention for years, and I have collected a host of facts concerning them which convince me that the biologists have made a mistake. They tell us that the platysma myoides, and the superficial muscles of that system, show descent from the panniculus carnosus of the cow and horse; that the rudimentary tail and ear muscles prove a pithecoid (ape) ancestry; and that the so-called rudimentary branchiæ indicate that the fishes are among our forefathers. I am of opinion that the reason is plainer and nearer at hand." A brief consideration of the subject leads him to believe that the muscular system is the chief power and the great mechanical means by which the fœtus is constructed, moulded, and formed into the shape it afterward assumes. From this stand-point one may readily see that these puzzling tissues, instead of being rudimentary ancestral heirlooms without a clearer meaning, are in reality the remains of that constructive machinery, common to all animals, which, with its nervous, muscular, and other agencies, controls the development of the fœtus, regulating the nourishment of the tissues, now producing growth, at another time causing atrophy, until the adult animal, with its proper species, variety, sex, and individuality, stands forth complete. "The umbilicus, the vestiges in the heart, the urachus, and the Wolffian body, are clearly remnants of embryonic function, and why not the vestigial muscles of the ear, scalp, skin, and coccyx?"

While, then, the muscular heart of the fœtus is, according to its laws, forcing blood onward to the growing tissues, the muscular tissue throughout the body is busy, in its own rhythmical way, modifying the force of flow and moulding into proper shape the newly formed matter. Thus, "in the human embryo, the so-called rudimentary muscles of the ear would be occupied forming the pinna and moulding the bones beneath. The occipito-frontalis would be shaping the skull to its rounded form. The spinal and coccygeal muscles would be employed rounding and curving the spinal column, and causing the coccyx to curve inward. In this work of forming the body all the muscles take part; afterward those not needed cease to grow or atrophy." These agencies have heretofore never been properly considered in works on embryonic physiology.

If the views of Dr. Cane are correct, one may easily see "that embryonic man possesses so-called rudimentary branchiæ, not because his ancestors were, but because he actually is, a fish living in water. He is placed in similar conditions to a fish; his blood must have oxygen, and, as the placental connection is not yet completed, the dissolved oxygen from the amniotic water passes through the attenuated membranes of the branchial folds and permits him to live."

So, he thinks, it is probable that the mammæ of the male may, in fœtal life, serve to elaborate fluids and substances to aid in the growth of the embryo, and in the adult continue their function as blood-glands.

Incomplete as his sketch is, he seeks to show briefly "how wide, interesting, and untrodden a field is opened up in the study of the mechanism of the making of man."

THE DISEASES OF THE UPRIGHT POSTURE.

WE are told in Holy Writ to observe and imitate the upright man, and this, in its spiritual sense, no doubt most attempt to do.

But in its physiological sense, Dr. Clevinger, of Chicago, and Dr. Eccles, of Brooklyn (*Brooklyn Medical Journal*), seem to think that uprightness is a mistake. The original mammalian type was that of a quadruped, which moved over the earth carrying its spinal axis more or less parallel to the surface on which it walked. The circulatory system and many of the ligamentous and visceral structures were developed on the theory, evidently, that this horizontal posture would be maintained. When man began to walk upright, with his originally quadrupedal organization, pathological changes resulted, and man continues to suffer, not from his fall, but from his rise.

The list of ills attributed by Dr. Eccles to the upright posture is long and interesting.

For example: Varicose veins and ulcers, piles, prolapsus ani, numerous malpositions of the womb and other pelvic organs, bow legs, numerous injuries to the viscera exposed by the upright posture, perityphlitis, spina bifida, goitre and cretinism, tumors.

The element of posture does not enter equally as a cause into all the foregoing cases, but Dr. Eccles shows that it does enter into some of them. His suggestions are interesting in connection with pathogenesis, but not

unfortunately, in connection with treatment. It is not advised that the human race attempt to revert to a quadrupedal mode of locomotion, in which we think the doctor most wise.

For, after all, it can easily be shown that the upright position is quite compatible with health and long life, and that, as a rule, the evils referred to can be averted by living temperate lives.

THE TREATMENT OF MENTAL DISEASE.

In the *American Journal of the Medical Sciences*, April, 1889, Dr. Clouston gives a paper full of thought and experience upon this important subject. Four cases out of five of recent mental disease have either sleeplessness, or active brain excitement, or morbid motor activity as part of their symptoms at some time. The temptation, therefore, to immoderate use of hypnotics, sedatives, and motor depressants is very great. In most kinds of mental disease the patient has reached his sad condition as a result not only of evil agencies operating upon his brain in his own lifetime, but also of inherited feebleness of brain tissue. The physician uses drugs merely to hold the more dangerous tendencies of disease in check, and to further the repair of tissue, until such time as the *vis medicatrix* shall have succeeded, under favorable hygienic conditions, in curing the disease.

The first considerations must be to nourish the patient, to restore his nervous energy, to regulate his functions, to direct his thoughts into healthy channels, to exercise his muscles and lower centres so as to get physiological and safe outlets for spare energy, to increase his self-control, to draw out his natural sense of pleasure and interest in surrounding objects. When using hypnotics and sedatives one should frequently ask himself: Are the patient's functions becoming disordered by them? Is the patient's mental state improved essentially by the sleep and quiet which they produce? Do the drugs interfere with the natural tendency to recovery? What is the expression of the patient's eyes and face after the drug-given sleep? Is he acquiring a drug habit? Is he losing his control of himself in any way, as a result of the use of the drugs? In insanity all drugs should be used experimentally at first, to see whether they produce real benefit, and the physician should omit them from time to time, to see how the patient does without them. A patient, insane or threatened with mental disease, should never be narcotized. In his article Dr. Clouston gives many interesting facts in regard to the use of drugs in mental disease.

THE PARTING OF LICHEN RUBER AND LICHEN PLANUS.

A question which has for some years been heating the minds of dermatological specialists is that of the identity of two somewhat rare and obscure forms of skin disease, viz., lichen ruber and lichen planus. These terms do not probably arouse the deeper emotions of the heart or convey any acutely definite clinical picture to the mind of the average practitioner. The question involved in their significance, however, has somewhat more than a superficial and cutaneous, it has a national, importance. It is not a mere matter of corium. The German writers have asserted, from the time of Hebra and Kaposi, that the two diseases are identical; while for several years a number of American dermatologists, and especially Dr. A. R. Robinson, have contended that they were separate diseases. A great strife has been waging—*sævit amor ferri*.

We have recently received from Dr. Robinson an elaborate monograph on the subject; while Dr. R. W. Taylor has contributed to the same topic in the *New York Medical Journal* of January 5th. We can safely say that these two communications, coming from such competent observers, settle the question between planus and ruber for all reasonable physicians, and that the American flag may again shake out its folds in triumph over the slower minds on the other side of the sea.

We shall give, first, Dr. Robinson's conclusions:

"1. In doubtful cases lichen planus and lichen ruber are to be diagnosticated not by the form of lesion alone, but also by the whole symptoms and course of the eruption.

"2. That lesions resembling in form those of lichen ruber and lichen planus exist in other diseases.

"3. That Unna's division into lichen planus, lichen obtusus, and lichen acuminatus is an unnecessary if not an incorrect division.

"4. That the cases reported by Unna were not examples of the disease described by Hebra.

"5. That the same is true of the cases reported by Boeck and Lavergne.

"6. That no cases have been reported which show absolutely, or even with probability, that lichen ruber and lichen planus are but two forms of the same disease.

"7. If an identity of etiology existed, such cases could have been reported, as lichen planus is a rather frequent disease.

"8. Finally, in the absence of proof of a tendency to a combination of the two forms of eruption, or to a transformation of the one form into the other form, either as an eruption or of individual lesions, and from the fact that the symptoms, course, prognosis, histology, and, to a certain extent, at least, the effect of certain drugs upon the eruption are different, there appears to be no good ground for the view that there is any relationship between lichen ruber and lichen planus.

Dr. Taylor gives the differential points in the two diseases, from which it will be seen that, as lichen ruber is a rare, and at the same time a serious disease, while lichen planus is not infrequent, it is very important that a correct diagnosis be made.

Dr. Taylor shows that while in lichen ruber the morbid changes begin in the superficial corneous layers, in lichen planus they begin in the substance of the corium; that while the former disease is not perceptibly inflammatory in its earlier stages, in the latter it begins in circumscribed inflammatory spots and patches; that while the former begins as small conical papules of neutral orange or slightly brownish-red color, which in due time become obtuse, then flat, with a slight central depression and very moderate desquamation, lichen planus begins in the form of red papules, not markedly conical, which flatten out into round, oval, angular, star-shaped outlines. In lichen ruber the papules reach their full development (a line or less in area) and never grow larger. Large patches are always formed by the multiplication and fusion of papules of uniform size. In lichen planus the papules increase by peripheral growth until usually they attain a diameter

of one to four lines. In the chronic stage of lichen ruber all trace of papules is lost, the surface being rather rough to the touch, and of a brownish-red color. In the chronic stage of lichen planus the epidermal hypertrophy results in dense, hard, uneven, sometimes rugose surfaces, even to a marked verrucous condition, with a deep red, even bluish-red, color. Lichen ruber invades the palms and soles in totality in uniform patches. Lichen planus is not common on the palms and soles, and when present consists of localized patches; lichen ruber attacks the nails, causing hypertrophy, impairs their nutrition, and may even destroy them. In lichen planus the nails are unaffected, except very rarely in inveterate cases by extension from the backs of the hands. Lichen ruber causes impairment of the nutrition and loss of hair, chiefly of the body. In lichen planus the hairs are unaffected. Lichen ruber is not known to attack the mucous membranes, while lichen planus does. Lichen ruber is attended with emaciation, and in inveterate cases causes death by exhaustion. In lichen planus there is no emaciation, nor, as a rule, any systemic reaction. While lichen planus is not uncommon, lichen ruber is, fortunately, a very rare disease.

THE OLIVE-OIL TREATMENT OF GALL-STONES.

THE revival of the olive-oil treatment of gall-stones is of recent date, and several physicians, both here and abroad, have published certain observations which apparently show that the oil is of service in the disease or condition known as cholelithiasis. The correctness of these observations has not been so generally accepted by the profession, however, that we can speak of this method of treatment as a fully recognized one.

Dr. W. T. Porter, of St. Louis (*The Weekly Medical Review*), analyzes the scientific evidence we have on this subject, and is forced to the conclusion that the reported cases are based on improper observations.

The oil has been generally given with the idea that its lubricating action would facilitate the passage of concretions. "But," says Dr. Porter, "a little reflection will show that the mucous membrane of the biliary ducts cannot be coated with oil. As everyone knows, the common bile-duct passes obliquely through the duodenal wall, running for three-fourths of an inch between the coats in such a way that lateral pressure on the inner coat of the intestine would close the valve-like aperture of the duct. The oil, therefore, could not enter the common bile-duct through a mouth made to gape by distention of the duodenum."

Another reason why olive-oil does not accomplish what is claimed for it is found in the circumstance that it is not possible to give a coating of oil to a membrane kept moist with watery secretion. The experimental evidence on this point is conclusive.

Turning now to the practical aspect of the subject, as it confronts the practitioner of medicine, we may say that, unless the diagnosis of a given case is quite above suspicion, it is manifestly improper to deduce therefrom any lesson relative to the therapeutic efficacy of the drug employed. In this connection it is pointed out by Dr. Porter that, unless gall-stones are actually found in the stools, the assumption of gall-stone colic is not warranted. It has been claimed that biliary concretions do appear after the use of olive-oil. But in those cases in which the alleged concretions were actually examined by competent persons, they were found to be composed of soap and free fatty acids, *i.e.*, the oil itself in an altered form.

The author thinks it probable that "in most instances in which oil has been given for biliary colic no pains have been taken to verify the diagnosis. Many medical men, if summoned to a patient who combined severe paroxysmal pain with jaundice, would at once diagnosticate obstruction from gall-stones, and would not search the stools. It is easy to see that a diagnosis so made is totally untrustworthy as a premise on which to base conclusions regarding the effects of treatment. The factors in such a diagnosis are (1) paroxysmal pain and (2) jaundice. It will be convenient to speak of these together. The majority of gall-stones are formed in the gall-bladder. If the stone is impacted in the cystic duct, bile continues to flow unimpeded through the hepatic duct and common duct. If the form of the stone be angular, the duct wherein it is impacted may not be completely blocked, and bile may pass. The stone may be impacted in the common duct for many hours, and jaundice be absent, for the icterode hue seldom appears in less than sixty or seventy hours after complete occlusion of the hepatic or common duct, though highly colored urine and pipe-clay stools may appear several hours earlier. Jaundice, therefore, may be absent in obstruction from gall-stones. Pain may be absent during the passage of even large gall-stones. When the common duct has been once dilated by a large stone, scores of smaller ones may subsequently pass without pain or jaundice. In such cases pain and jaundice may both be absent. Large stones may pass quite unknown to the patient.

"On the other hand, the symptoms of the passage of stones may be present in cases that have nothing to do with cholelithiasis. Hydatid cysts, for example, have been known to give rise to such symptoms. Acute hepatitis, and even hepatic neoplasms "have likewise produced them. Further than this, intestinal worms or inspissated bile may block up the ducts and cause all the symptoms of hepatic colic. The pains of pleurisy, pleurodynia, intercostal neuralgia, gastric dyspepsia, intestinal and renal colic, are often referred by patients to the liver. On the other hand, pains thought to arise in the stomach are frequently due to gall-stones. Ulcer of the duodenum, near the opening of the common duct, has been known to produce spasmodic abdominal pain followed by jaundice, and the cicatrix of such an ulcer may completely obliterate the orifice of the common duct. The symptomatic value of jaundice is much lessened by the knowledge that jaundice may be brought about in so many and in such diverse ways. Jaundice and vomiting may undoubtedly follow the sudden contraction of the diaphragm that sometimes accompanies violent mental emotions."

Altogether it seems to us that the case against the vaunted utility of olive-oil in gall-stone colic, as presented by Dr. Porter, is a strong one. The author's conclusions bear transcribing, and are as follows: "1. No protecting or lubricating action is exerted by oil in those parts of the intestinal tract whose contents are fluid. 2. No positive diagnosis of gall-stone colic is possible unless a stone is found in the fæces, or unless an exploratory

operation is done. 3. There is reason to suppose that in many of the cases of hepatic colic said to have been benefited by olive-oil, the diagnosis has not been verified by the finding of gall-stones in the stools. 4. The pathological condition which is the immediate source of danger in gall-stone colic is the contractile spasm excited by the stone. 5. Treatment should be directed to relieve this spasm by chloroform, and moist heat internally and externally where paroxysmal pain or exploratory puncture makes the diagnosis probable, and by moist heat alone in cases where slight pain makes the diagnosis less probable. 6. Hot olive-oil is of assistance only because of its moist heat, and nothing is gained by its use which is not secured in equal measure by the adminstration of hot water. 7. The so-called olive-oil treatment should be abandoned, because it implies a special virtue in the oil which the oil does not possess, and a reliance on which tends to prevent the use of rational methods."

CANCER AND NERVOUS EXHAUSTION.

THE removal of a faithful and efficient officer from his position while he was dying from an insidious disease has naturally aroused resentment and indignation among right-feeling men. It seems a pity that the necessities of politics could not have delayed the removal of the late Postmaster of this city a few weeks longer.

Nevertheless, it is hardly right to make him too much of a martyr, or intimate that he was killed by the excessive work and anxiety of his position. His death was caused, it is said, by cancer of the stomach, a disease not due, it is now believed, to emotional causes or nervous over-strain.

News of the Week.

ATHLETICS AND SCHOLARSHIP.—Professor Richards, of Yale College, has made a study of the records of 2,425 students, in order to determine, if possible, the relations of athletics in Yale to scholarship. The general result is that the athletes fall slightly behind the non-athletes in scholarship, but not so much as to demand a suppression of such exercises. In some branches of athletic exercises the students who engage in the sports are above the average of the non-athletes in scholarship.

A TABLET IN COMMEMORATION OF A SURGICAL OPERATION.—On April 17th, in the Anatomical Theatre, Bologna, a memorial tablet was unveiled in commemoration of Professor Pietro Loreta's first conception and performance, August 26, 1887, of his now famous operation of resection of the liver. A vast assembly of students, clinicians from all parts of Italy, and of the general public were present. A splendidly illuminated album was also presented to Professor Loreta, at his own house, in commemoration of his recent return to Parliament as member for the first division of Bologna.

DEATH OF A MEDICAL JOURNALIST.—Dr. Paul Bricon, a prominent member of the staff of the *Progrès Médical*, died on Sunday, April 7th, of heart disease. He was born in Paris on August 1, 1848, and began the study of medicine in the University of Berne. After studying for some time at Würzburg, he graduated at Strasburg, and afterward at Geneva, where he was assistant to Dr. Zahn, the professor of pathology. In 1879 he returned to France, and in 1882 obtained the degree of doctor of medicine for the third time from his native faculty of Paris. He was a favorite of Dr. Bourneville's, who invited him to become a colleague on the staff of the *Progrès Médical*, and with whom he collaborated in the well-known work, "Manuel des Injections Sous-cutanées," which has been translated into English, Spanish, and Italian. He was also the author of a "Manuel de Technique des Autopsies."

DR. THOMAS LAYTON, a distinguished physician of New Orleans, died on May 5th, of heart disease, quite suddenly. He was a native of that city. He was educated in the Jesuits' College of New Orleans, and then went to Paris to complete his studies in medicine. Just before graduating, the Italian war occurring, he offered his services to the Pope and served in the medical corps of his army. Returning to New Orleans, he took an active part in all humane and philanthropic works. As head of the Charity Hospital for many years, he inaugurated the ambulance service.

THE NEW BUILDING OF THE NEW YORK ACADEMY OF MEDICINE.—The building of the New York Academy of Medicine, which is to be erected immediately upon property lately purchased in Forty-third Street, near Fifth Avenue, has been designed by R. H. Robertson. The lot upon which it will stand is seventy-five feet wide and one hundred feet deep, and when the new home of the Academy is finished, it will be one of the most complete structures of its kind in the city. The building will be five stories in height, and will also have a gable story. The material used in the construction of the front will be a brownish-red Kibbe stone, both rock-faced and dressed, and brick. The style of architecture is Romanesque. The first and second stories have large square windows in pairs, with columns between; the third and fourth floors will be lighted by arched windows, and the windows in the gable are square. The entrance is to be in the end nearest Fifth Avenue, and two large doors are divided by a massive stone column. Above the door are small square windows, and above them a stone balustrade. The basement of the building will contain the kitchen, lavatories, a room for unpacking books, and machinery. The first story is in itself a well-appointed club-house. The two doors from the street open into a spacious tiled vestibule, from which a door leads into an inner vestibule, opening into a large hall. On the right are a reception-room, a coat-room, an elevator, and stairs. On the left of the hall are the committee or reading-room, and the smoking-room, the latter being 36x26 feet. These rooms are lighted by the big windows in the front of the building. The rear half of the floor is devoted to a large assembly-room, 57x42 feet, and a dining-room, 31x28 feet. These two rooms are separated by a rolling partition, and they can be thrown into one at any time when required for large meetings or a largely attended dinner. One and a half stories are taken for this part of the house, and the rooms are twenty-six feet high. On each side are air-shafts, and by means of a glass arch a flood of light is let in at each end of the rooms. The dining-room is treated with a peaked ceiling, which will be very effective. The

half story in front of the building, which is eleven feet high, is to be used for committee-rooms, etc. The third story will contain the library. The Academy has long wanted room for its many valuable books, and the accommodations provided in its new house will be entirely adequate. On this floor, taking up the whole rear and part of the front, are the reference library and the "stock" room. These two rooms run through one story and a half. In the rest of the front is a reading-room one story high, and above it is another. In the front of the fourth story will be the pathological section and two specimen-rooms; and in the rear will be three large section-rooms and an apparatus-room. On the top floor will be the librarian's apartments, the janitor's quarters, and a microscopy-room. The building, when completed, will cost about one hundred and forty thousand dollars.

A New Specific Fever, which is called pleuro-pneumonic fever, has recently been described by Dr. E. Ballard. An epidemic of it occurred at Middlesborough, England, in July last. It is an infectious and contagious malady, running a rapid course, and having, according to Dr. E. Klein, a new and special bacillus as its cause.

The Sixth Italian Surgical Congress was held at Bologna, beginning April 16th (*The Lancet*). Professor Ceccherelli opened the proceedings with a memoir on "Surgery in Tubercular Peritonitis," and described four cases on which he had operated with complete success. He was followed by Professor Ruggi, who reported on the "Statistics of Laparotomy as Performed during the last Twelve Months." He announced a series of 115 operations, all successful except eight, of which he characterized the unfavorable conditions. In the afternoon sitting Dr. Angelini described a successful case of removal of an ovarian cystoma from a woman in her fifth month of pregnancy; and then Professor d' Antona gave a list of thirty-two successful ovariectomies, the most interesting of which was one performed for hystero-epilepsy. After him came Professor Pucci with a *catalogue raisonné* of laparotomies performed in the clinique of Professor Loreta. Two of these—one for stenosis of the pylorus, the other for stenosis of the cardia—proved highly instructive, Professor Loreta having proceeded by the method of divulsion devised by himself, with the most gratifying results. The next paper, of great interest, was that of Professor Durante, on "Removal of the Cæcum for Tuberculosis," only a few cases of which operation are recorded in surgical annals. The rapidity and completeness of the cure was one of its most gratifying features. Next day (the 17th) Professor Postemski, of Rome, resumed the subject of laparotomy, his thesis being "Laparotomia Diagnostica e Curativa nei Traumi dell' Addome" ("Laparotomy, Diagnostic and Curative in Wounds of the Abdomen"). In such cases, he said, the sooner surgical interference is practised the better. Of the twenty-three patients on whom he performed the operation, sixteen were suffering from wounds. Seventeen out of the twenty-three operations were successful, and he drew particular attention to one of the patients, who labored under a serious wound of the liver, and another not less seriously injured in the bladder. His success has been such that he has had constructed, in the Consolazione Hospital at Rome, a special ward, fitted up with every surgical and scientific appliance for the prompt practice of laparotomy. Among other papers discussed in the forenoon and afternoon sittings, were Professor d' Antona's paper on "Estirpazione di un Aneurisma Arterio-venoso della Femorale"—a most interesting specimen of surgical reasoning and practice; and another memoir by the same Neapolitan professor, "Sulla Milza Mobile ed Ipertrofica con Splenectomia e Guarigione" ("On Movable and Hypertrophic Slpeen, with Splenectomy and Cure"). On a similar thesis, "Sugli Effetti dell' Estirpazione della Milza nell' Momo," Professor Ceci read an admirable paper, as also one on "Extirpation of the Spheno-palatine Ganglion for Neuralgia;" while Professors Tizzoni and Poggi exhibited a dog in which, by surgical means, they had reconstructed the bladder—an achievement which attracted much attention and criticism. The concluding day (the 18th) was in some respects the most important of the three. Professor Ruggi read an elaborate chemico-pathological study of a patient on whom partial resection of the liver had been performed—an operation done for the first time by Professor Loreta. This case by Professor Ruggi was the second, and was highly successful. The woman was visited and examined by the members of the Congress. An interesting feature of the cure was the slow cicatrization, which, from experiments made on animals, Professor Ruggi saw reason to attribute to the slow continuous passage of the bile.

The Physician's Fee.—A decision was recently given in a suit for payment for services brought by Dr. Lange, of this city. Judge Brady, of the New York City Supreme Court, decided that, in an action by a surgeon for professional services, the plaintiff has a right to show that his standing in the profession is high as bearing upon the question of the measure of his compensation. The judge further said: "There is also evidence tending to establish a custom or rule of guidance as to charges of physicians for services rendered, and which makes the amount dependent upon the means of the patient—his financial ability or condition. This is a benevolent practice, which does not affect the abstract question of value, nor impose any legal obligation to adopt it, and cannot be said to be universal. Indeed, there does not seem to be any standard by which, in the application of the rule, the amount to be paid can be ascertained. Each case is under the special disposition of the surgeon or physician attending, and he is to decide as to the reduction to be made on account of the circumstances of his patient; and therefore, when the amount is in dispute, it follows that it is to be determined by proofs to be given on either side. The measure of compensation must be controlled more or less by ability in all the professions, and the service rendered by its responsibilities and success."

The Ohio State Medical Society.—The Forty-fourth Annual Meeting of the Ohio State Medical Society will be held at Youngstown, O., May 22, 23, and 24, 1889.

The Toner Lecture.—Professor Harrison Allen, of Philadelphia, will deliver the next Toner lecture in Washington, at the National Museum, on the evening of the 20th inst. The subject is: "The Clinical Study of the Skull, especially undertaken in Connection with the Morbid Conditions of the Jaws and Nasal Chambers."

THE OPENING OF JOHNS HOPKINS HOSPITAL, BALTIMORE.

(Special Report from our Baltimore Correspondent.)

THE formal opening of the Johns Hopkins Hospital took place on Tuesday, May 7th. For many years the medical profession of Baltimore has been looking forward with great interest to the establishment of this great institution. The deliberation which was exhibited by those in charge of the endowment fund, of three and a half millions of dollars, in its expenditure, and the careful manner in which the work upon the hospital buildings was done, indicated clearly that the hospital, when fully completed would represent the best and latest ideas in the possession of the scientific and medical world. Upon an eminence in the eastern section of the city the necessary buildings have been very slowly erected, until seventeen of them now stand complete, surrounded by beautiful grounds and gardens. At eleven o'clock on the morning of May 7th your correspondent, holding a ticket of admission to the opening ceremonies, reached the hospital and was ushered into the fine "administration building," which stands in the midst of the rank of buildings which face upon the green parks of Broadway. Entering, he found himself in a beautiful, lofty, many-sided hall, furnished with two galleries and decorated with flags and flowers. The company of distinguished guests present filled the hall and gallery and every available space in the adjacent rooms from which a view of the speakers could be obtained. Many eminent strangers joined with the favored residents of the city in welcoming this noble institution, which for many generations to come will be the pride of the State in which it has made its home.

After prayer by one of Baltimore's most revered pastors, and an interlude from an orchestra concealed in one of the many radiating halls, a short opening address was delivered by the President of the Board of Trustees, Mr. King, who has throughout watched most carefully over the birth and growth of this great establishment. At its conclusion he introduced Dr. Billings, who spoke at some length of the designs of Mr. Hopkins, the endeavors of his trustees to faithfully embody them, the various stages of the work, and the great results which the medical profession and the world at large expected from this hospital and its corps of medical teachers and investigators. In this work Dr. Billings had been the master-workman, and to his intelligent exertions is due the almost perfect result which has been attained.

After a brief intermission President Gilman, of the Johns Hopkins University, who is at present supervising the organization of the hospital corps and the equipment of its various departments, spoke in somewhat the same strain:

"Thirteen years ago, during the centennial celebration, of Independence Day, the university founded by Johns Hopkins began its work, and now, as we commemorate a completed century of constitutional life, the hospital, gift of the same donor, throws open its doors. These buildings are henceforth consecrated to the ministry of mercy and the restoration of health. That large-minded citizen of Maryland found two words adequate to his great ideas. 'University' and 'Hospital' were his chosen terms, and he linked them together by this significant phrase: "Bear constantly in mind that it is my wish and purpose that the hospital shall ultimately form a part of the medical school of that university for which I have made ample provision in my will.' Time may efface the personality of the founder, as it has effaced the personality of Rahere, the founder of St. Bartholomew's, but the beneficence of Johns Hopkins will last for centuries, and gratitude will cherish the memory of his broad views, his great liberality, his wise and beneficent purposes.

"Nor will posterity forget the Board upon which he bestowed this trust. During fifteen years the public has had the unpaid services of twelve of the most capable citizens of Baltimore, who have endeavored, under the leadership of their president, Francis T. King, to ascertain, by correspondence, travel, reading, and by consultation with experts in medicine, surgery, nursing, architecture, education, and administration, the most enlightened views of the civilized world with regard to the construction and management of hospitals. They have built these seventeen buildings from the income of the fund, and have even increased the principal gift. They have constantly benefited by the professional advice of the distinguished surgeon Dr. Billings. The noise of the hammer has ceased; the healing ministry begins.

"All the signs of the times point to a new era in the history of mankind. All the sciences are leading up to a better understanding of the laws of life, to a true anthropology and the consequent improvement of the physical, mental, and moral powers of man. Preventive medicine promises to do more and more for mankind. To the attainment of these noble aims, 'the relief of suffering and the advancement of knowledge,' the foundations of Johns Hopkins are forever set apart. On the one hand stands the university, where education in the liberal arts and sciences is provided, and where research is liberally encouraged; on the other hand stands the hospital, where all that art and science can contribute to the relief of sickness and pain is bountifully provided. An institute of medicine and surgery, a college of physicians and surgeons, a medical school, the office of which shall be to promote the training of young physicians and the encouragement of medical science, is imperatively needed. Is it too much to say that there is not such an opportunity on the face of the globe for another Peabody, or another Hopkins, to benefit his fellow-men.

"'The university needs all it has, and more, to carry on the non-professional courses to which its funds are appropriated. The hospital is the house of mercy, not the hall of philosophy. But in close alliance with both these foundations there is a place for a school of medicine which may bear its founder's name. This grateful city should no longer delay placing upon one of the squares, near the monument of Washington, the figure of Johns Hopkins, with designs to typify the ideas which underlie his gifts—'the advancement of knowledge and the relief of suffering.'

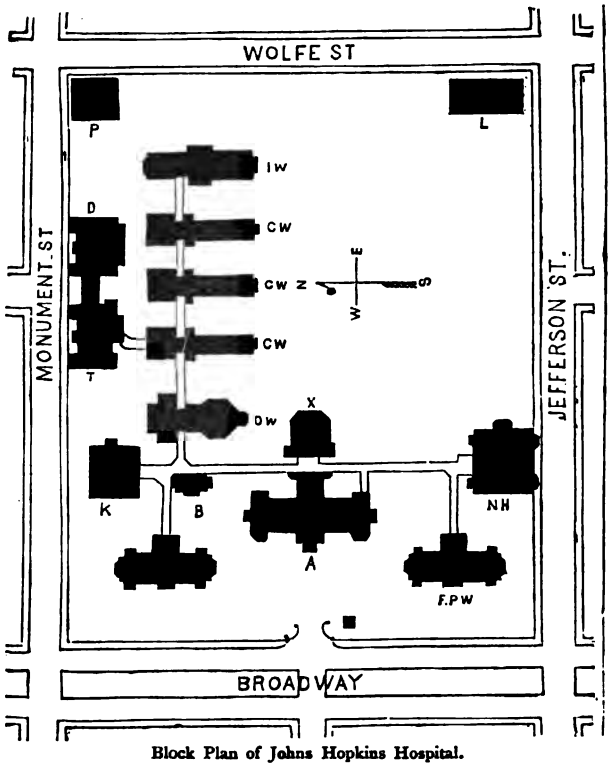
"Upon one hill of Baltimore rises a temple 'whose guardian crest, the silent cross,' is an emblem of the Christian faith; upon another a lofty column reminds us of the patriot's hope; upon a third the Hotel Dieu is placed—the house of charity. Significant triad! 'Here abideth faith, hope, and charity, but the greatest of these is charity.'"

After the conclusion of the address of President Gilman, the hospital was formally declared open by the Governor of the State of Maryland. The guests were then invited to inspect the buildings, and spent some time very pleasantly in observing, in one building after another, the system of heating, ventilation, etc., and the peculiarities in the construction of the walls of the wards, which are designed to permit the easy removal and destruction of all disease-products which may adhere to them. The arrangements for the accommodation of resident students are, as one of the speakers of the morning expressed it, "equal in every respect to those of a first-class hotel." The building for the accommodation of the nurses and the students of the proposed training-school for female nurses, with its kitchen, lecture-room, and library, deserved especial attention. The working of the dispensary, which will be shortly opened will, be watched with interest, as it has been promised that "all possible precaution will be used to avoid pauperizing the patients." Any institution which will solve this problem of medical charity without pauperization will deserve the thanks of the medical public.

DESCRIPTION OF THE HOSPITAL.

The hospital grounds, which front on Broadway, and are bounded on the other sides by Monument, Wolfe,

and Jefferson Streets, are 709 feet in length, and extend back a distance of 856 feet, covering four city blocks, an area of nearly fourteen acres. The hospital is built on the pavilion system, all the separate buildings being connected by covered corridors ten feet in width. The pavilions are two stories and an attic in height, the wards being in the second story. The first story, or basement, is raised slightly above the level of the ground, and is nine feet clear from floor to ceiling. The flooring is of artificial stone. The corridors connecting the different buildings open on this floor. The first floor contains only the ventilating and heating apparatus. The second story contains the wards, all of which open out on to the roof of the corridors. This roof is flat and provided with a railing, and is used ordinarily as a means of communication between the pavilions, and also as a place of exercise for such of the patients as are able to be about. By this plan each ward is practically an isolated building, the corridor coming only up to the level of the floor, and no obstruction is offered to the free access of air and sunlight. Yet in stormy weather the officers of the institution can pass from one building to another through the covered corridors without exposure. Yet before entering the ward they are obliged to ascend the stairway through the main hall, which is so thoroughly ventilated as to be practically in the open air.



Block Plan of Johns Hopkins Hospital.

A.—Administration Building.
X.—Apothecary's Building.
M.P.W.—Male Pay-ward.
F.P.W.—Female Pay-ward.
N.H.—Nurses' Home.
K.—Kitchen.
B.—Bath House.
O.W.—Octagon Ward.
C.W.—Common Ward.
I.W.—Isolating Ward.
T.—Amphitheatre.
D.—Dispensary.
P.—Pathological Building.
L.—Laundry.

The wards are of two kinds, rectangular and octagon. The oblong wards are each somewhat over 90 feet long, by about 30 feet wide, with a height of 16 feet. Each ward contains twenty-four beds, twelve on each side, with a window between each bed. There is a wall space of 7½ feet for each bed. At one end of the ward is a large hall, the main feature of which is the enormous aspirating shaft in its centre. Opening into the hall are the water-closets, lavatories, nurse's closets, and stairway. On the opposite side of the hall are the dining-room, and two or three other rooms with two beds each, for the reception of patients for whom it is desired to secure a measure of isolation for any reason.

The octagonal wards are two stories in height. These wards are divided into four rooms, providing a measure of isolation for the patients. At the southern part of each octagonal ward is a solarium. These wards are also built at the southern end of the pavilion, so as to obtain the greatest possible amount of sunlight.

Isolating wards are provided for the accommodation of patients suffering from contagious diseases. They are entered from the corridor through double doors. Some of them have a perforated floor (Wiman's system) to provide for extra heating, if occasion requires. In these wards each patient has a separate room, and the ventilation, instead of being effected by a single aspirating shaft for the whole building, as in the ordinary wards, is obtained by a separate shaft for each room.

There are no elevators in any of the pavilions devoted to the lodgement of the sick, but the stairways are broad and with a gentle incline, so that patients can be carried up on stretchers without discomfort to them or fatigue to the porters. A consideration of the ventilating problem is said to have been the main reason for not having elevators, it being feared that the shafts might serve for the conduction of foul air.

The pay-wards differ but little in their appointments from the free wards, except that each patient has a room to himself. They are furnished plainly, with chairs, bureau, washstand, wardrobe, and an iron bedstead. Each room communicates with the central hall, in which, as in the other pavilions, the aspirating shaft is found. At present the ward for men only is open, but the women's ward is building, and will probably be ready for the reception of patients in the autumn.

At present there are accommodations for about two hundred and thirty patients; but when the additional wards which it is proposed to build are completed the number of beds will be nearly four hundred, which was the limit set by Johns Hopkins himself for the capacity of the hospital.

The operating ward is in a building containing the amphitheatre, lecture-rooms, accident ward, nurses' rooms, a room in which patients are anæsthetized before the operation, and another room to which they are carried after the operation, and where they remain until such a time as they are in condition to be returned to the general ward. The amphitheatre has seats for two hundred students.

The out-door department occupies a building by itself, and contains a large waiting-room, drug-room, eleven separate rooms for the different classes, lavatories, and water-closets.

The administration building is a three-story structure containing the board meeting-room, apartments for the medical director, and resident physicians' and students' quarters. The board-room is modelled after Johns Hopkins library, containing his books and the same furniture that he used in his library. The quarters of the resident physicians and students comprise a reading-room, dining-room, bedrooms, bath-rooms, and water-closets. In the medical director's office are electric bells and speaking-tubes leading to each of the pavilions and separate buildings, a pneumatic clock connecting with all the other clocks in the institution, by means of which all indicate precisely the same time, and what is called a telemetre. The latter is an electric appliance by means of which the temperature of the different pavilions is registered, so that the director can tell, by merely looking at the indicator, whether the temperature in any ward, or even any part of it, is too high or too low. If he sees that it is too high or too low he has only to direct the orderly in charge of that ward, through the speaking-tube, to open or close the damper regulating the supply of fresh air circulating around the steam coils.

The apothecary's building is also three stories in height, and contains the drug-room, indoor dispensary, quarters for the druggist and his assistants, and on the upper floors rooms for the female servants.

There are separate buildings for the men's and women's bath-houses. These contain conveniences for the

administration of all sorts of baths—electric, mercury, Russian, Turkish, needle, etc. Everywhere throughout the institution the facilities for bathing are most abundant, and every encouragement is offered to the officers and attendants, both lay and medical, to observe the strictest cleanliness in their persons as well as about the buildings.

Besides the nurses' kitchens connected with each ward, which are used only for preparing food that may be required at night, or for warming broths and the like, there is a special building devoted to culinary purposes. This building is three stories high, with store-rooms, kitchen, dining-rooms for the employees, and sleeping-rooms for the cooks. The hot-water and steam-boilers are under Monument Street. They supply steam for the kitchen and for the steam-tables in the nurses' kitchens, and hot water for the heating apparatus in all the buildings. The pumps for filling the reserve tanks on the roof of the administration building are also located here.

The laundry is a one-story building, standing on one corner of the hospital grounds apart from all the other buildings. In the cellar is a place for disinfecting bed-linen and clothing; on the ground floor is the laundry, fitted up with all the latest and most approved forms of tubs, washing-machines, and wringers; and on the flat roof are lines for drying the clothes and giving them a good sunning and airing in fair weather.

The mortuary occupies another corner of the lot, and is also disconnected from the other buildings. It is two stories in height, the first floor being taken up with an amphitheatre for conducting autopsies, a pathological laboratory, and a room in which funeral services may be held. Above are the museum and histological laboratory. The nurses have a house of their own, standing apart from the other buildings. The house is four stories high, and contains about fifty bedrooms, a parlor, reading-room and library, dining-room, kitchen, and lecture-room.

In addition to the buildings already constructed it is proposed to erect a chapel, some four or five pavilions, and a greenhouse. The chapel will front on Wolfe Street, in the centre of the block between the mortuary and the laundry.

The buildings are heated by hot-water coils placed in the basement. The fresh air enters the chambers containing these coils, and after being warmed passes up to the wards and enters them through numerous registers in the walls near the floor. In the small rooms there are also open grate-fires. Ventilation is provided for by ducts eading to the large aspirating shaft in the main hall of each pavilion, and by other outlets in the floor under each bed, which also lead to the main shaft. The latter is octagonal in shape and nearly five feet in diameter. An ascending current is made by a coil of pipes placed in the shaft, a little above the level of the roof. In addition to the ordinary ventilating outlets there are also outlets in the ceiling which can be opened when a specially rapid and thorough renewal of air is deemed necessary. It is believed that, by these arrangements, the air in the wards will be entirely changed three or four times each hour, without the creation of any sensible draught. Fans in the basement will cause a more rapid movement of the air in damp weather when the atmosphere is heavy. As before mentioned, the temperature in each ward is constantly recorded in the office of the medical director by means of the telemetre.

The plumbing arrangements are in keeping with the other appointments, sightliness being made to yield to cleanliness and safety. All the pipes are exposed and can be inspected at all times without removing any woodwork or screens. The walls join each other, and the floor and ceiling, without angles; the floors are of hard-wood, oiled, and great care has been taken in the construction of all the buildings that no places may exist where dust may collect. Every part of the walls and floors of the wards, rooms, halls, and closets is accessible, and can be readily cleared of all accumulation of dirt by means of a damp cloth.

Most of the buildings are of brick, with blue-stone trimmings. The cost of construction has been something over two million dollars, and there is an endowment of $3,000,000 to provide for the running expenses of the hospital. The buildings occupy an area of about four acres, leaving ten acres of open ground between and around the pavilions. The medical school is attached to the university, though the clinical instruction will be given in the hospital. The main objects of the hospital, as laid down by Johns Hopkins himself, are the care of the indigent sick, the training of nurses, and the advancement of medical science. And, as far as buildings can go in the accomplishment of these objects, the founder, were he living to-day, would have little cause for concern as to the realization of his hopes.

In the evening, at eight o'clock, the Trustees gave, in the parlors of the Mount Vernon Hotel—the present residence of President Gilman—a select and very enjoyable reception in honor of the visitors who had come from a distance to be present at the opening of the hospital.

It is to be hoped that the hospital will follow the example of the university in seizing every opportunity to repeat these pleasant little gatherings of its friends. Promise has been already given that in a few days the professors of the hospital will invite the physicians of the Medical Societies to a social assembly within its walls.

During the present week the buildings will be thrown open from day to day for the inspection of the various classes of citizens of Baltimore; first to physicians, teachers, and other professional men; then, in due order, to all who feel an interest in this great institution. Judging from the interest shown by the daily papers—those great interpreters and moulders of public thought—the desire to inspect the hospital will be a very general one.

For the past decade the opening of the Johns Hopkins Hospital and Medical School has been viewed with very great interest, by the better educated physicians of Baltimore, as a great unknown quantity which must necessarily enter into the equation of professional life and advancement of each and all, especially those whose place in the favor of the public was not yet secure. That these institutions would be of great benefit to the profession and the public was very evident, for an endowed school and a rich hospital having, as one of its objects, the training of resident students, must necessarily advance the standard of medical education, and this would be an unalloyed blessing. But who would be employed in the school and hospital? This was the question. Would numbers of strangers be brought in from other cities and from abroad, and, aided by the prestige of their professorships, drive out of practice those who had by life-long labor won a way to the respect of the public? Hitherto these questions have not been answered.

The Medical School is yet a thing apparently of the distant future. It is to be supported by the university (not the hospital) foundation; the university foundation rests upon the Baltimore and Ohio Railroad; which is—so to speak—in a delicate condition of health. So only such professors may be appointed as may in some way be supposed to hold positions in connection with the hospital. The actions of those in authority seem to indicate that the professorships will be filled with men from large hospitals and schools of other cities and of foreign countries, and that these will be allowed to bring their favorite assistants with them. The interest which Baltimore physicians feel in the matter is, therefore, of a general and broadly benevolent sort. The work done in the hospital will probably be of the strictly scientific quality, and, judging from that already done in the laboratories now open, it will be a credit to the city. Earnest physicians hope that the introduction of this new element into medical life here will enable the profession to shake off the trammels of ignorance and of clique, and to assume the position which is by right its own. None

feel with greater force than the young doctors of our own city the disgrace which has come upon the profession from the avarice and negligence of those who constitute the medical faculties of our colleges; who turn out, year by year, hundreds of ignorant and incompetent physicians, and who, actively or passively, resist every effort to raise the standard of graduation. Professor Osler has already, in his address before the Medical and Chirurgical Faculty of Maryland, indicated his determination, which we hope may be indorsed by his colleagues, to use every right means to secure a law which will take the right to license to practise away from the colleges, and to give it to a properly appointed State Board. In this endeavor he will receive warm support from many who wish Maryland to resume, in the rank of sister States, the honorable position which the fathers of medicine gave her.

On the whole, this has been a day which will be long remembered in this city, as marking a new era in medicine, and ushering in a period of unprecedented progress.

Reviews and Notices of Books.

THE PATHOLOGY AND TREATMENT OF DISPLACEMENTS OF THE UTERUS. By DR. B. S. SCHULTZE, Professor of Gynecology, Director of the Lying-in Institution and of the Gynecological Clinic in Jena. Translated from the German, and edited respectively by JAMES J. MACAN, M.A., M.R.C.S., and ARTHUR V. MACAN, M.B.M.Ch., Master of Rotunda Hospital, Dublin. 8vo, pp. 378. New York: D. Appleton & Co. 1888.

THIS treatise is one of the most practical and scientific on the difficult subject of which it treats that has appeared for a long time. With many practitioners displacements of the uterus are bugbears in practice, and the dreadful and heretofore uncertain pessary challenged the question, "to be or not to be." The reason for this is partly due to the fact that displacements have not been studied as a rule from a physiological and pathological stand-point. The normal and abnormal positions have not been distinctly and scientifically defined. This book does it in a very satisfactory manner. The great variety of normal positions are noted, the various departures therefrom are carefully studied, the value of bimanual examination clearly set forth, the utility of proper pessaries duly demonstrated and illustrated, while the strictly surgically operative procedures have a secondary place. The great and leading feature of the work is the masterly study of the pathological conditions which directly and indirectly bring about displacements. From such a stand-point it can be studied with great interest by every general practitioner, who does much of the ordinary gynecological work.

TREATISE ON THE DISEASES OF WOMEN. FOR THE USE OF STUDENTS AND PRACTITIONERS. By ALEXANDER J. C. SKENE, M.D., Professor of Gynecology in the Long Island College Hospital, Brooklyn, N. Y., etc. 8vo, pp. 966. New York: D. Appleton & Co. 1888.

DR. SKENE'S book is a valuable one, as giving the results of personal practical experience over the entire range of gynecology. The arrangement of the work is quite satisfactory, while his method of study and the conclusions drawn therefrom are logically accurate, if not always convincing. In these days of urgent and ingenious advocacy of surgical procedures as the only ones to be thought of in the treatment of gynecological difficulties, it is refreshing to read an author, an acknowledged expert in his line, leaning toward conservatism with the knife and scissors. In reparative operations about the vagina, cervix uteri, and bladder, this is especially noticeable in the pains taken to steer between the necessary and the unnecessary procedures. In carrying out such plans the author often manifests an ingenious as well as conservative turn in saving tissue, and in thus proportionately militating against further loss of function. In such a treatise it is to be expected that much ground already well trodden will be renewed, but this is very judiciously and systematically done in accordance with the advanced and accepted views of the present day. His preferences for particular lines of treatment are fairly put, and will have their due weight not only with the student and beginner but with the specialist, for, underlying all injunctions *pro* and *con*, the reader is made to feel that there is a foundation of extended and well-worked personal experience upon which firm convictions securely rest. Growing out of the author's studies, also, there is often to be noticed a positiveness of statement and force of expression which leave no doubt in the mind of the reader of his meaning and intent. Without disparaging the other parts of the work, it is safe to say that the chapters on diseases of the urethra and bladder are particularly well digested, and rich with practical suggestions as to operative and other remedial measures. The illustrations are remarkably good, and serve an admirable purpose of elucidating the text, terse and to the point as it is. The representations of different steps of many of the operations, otherwise difficult to comprehend, are particularly successful, and convey to the mind of the reader the essential points in the technique of the procedures. This fact is one of the many commendable features of the work. As a whole, the work will have a healthful and lasting influence upon the profession in placing advanced gynecology on a firm and rational basis of practice. As such it is destined to take its place in the front rank of text-books on the subject.

EXPLORATION OF THE CHEST IN HEALTH AND DISEASE. By STEPHEN SMITH BURT, M.D., Professor Clinical Medicine and Physical Diagnosis at the New York Post-graduate Medical School, etc. 12mo, pp. 206. New York: D. Appleton & Co. 1889.

THESE chapters comprise the author's system of teaching physical diagnosis at the above-named institution. They cover the classical topics of this department of medical teaching with the usual modifications of experience. Especially commendable is the author's insistence upon the fact that "precision in diagnosis is more surely attained by treating each sign as subordinate to the various combinations of signs which are found in the different maladies." A chapter on "Calormetation," or surface thermometry, is an unusual addition to the book, which, as a whole, is a most excellent one for a beginner. It is based on the fact that the foundation for such study is a knowledge of the topography of the normal chest.

THE NATIONAL FORMULARY OF UNOFFICINAL PREPARATIONS. First issue. By authority of the American Pharmaceutical Association. Published by the American Pharmaceutical Association. 1888.

THIS is an attempt to establish a uniformity in the composition of several preparations which are not recognized by the Pharmacopœia, but which are, nevertheless, more or less frequently prescribed by physicians. It would be an advantage to the physician, no less than to the druggist, if these various preparations were made according to definite formulæ, and to bring about so desirable a result is the object of the compilers of this "Formulary."

FRACTURE OF THE SPINE: its Immediate Treatment by Rectification of the Deformity and Fixation by Plaster-of-Paris Jacket. By HERBERT L. BURRELL, M.D., Surgeon to Carney Hospital; Surgeon to Out-patients, Boston City Hospital; Assistant Surgeon, Boston Children's Hospital; Demonstrator of Bandaging and Apparatus in Harvard University.

THIS is a reprint of a paper read at the Annual Meeting of the Massachusetts Medical Society in June, 1887, and is mainly an analysis of eighty-two cases of fracture of the spine treated at the Boston City Hospital.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 18, 1889.

ALFRED L. LOOMIS, M.D., IN THE CHAIR.

DR. E. F. BRUSH read a paper entitled,

THE RELATIONSHIP EXISTING BETWEEN HUMAN AND BOVINE TUBERCULOSIS,

which consisted chiefly of an analytical study of the writings of travellers and historians regarding the prevalence of tuberculosis among men, where cattle were domesticated, and its absence where the flesh and milk of cattle were not used.

The handsomest cattle were seen among the inbred, and among these tuberculosis was most common. It had been supposed that this disease in the human race was the result of civilization, but observation showed that among certain uncivilized tribes it was equally common. Nor was its existence due to climate or locality; every known part of the globe, with few exceptions, was its habitat. After studying the question of climate, etc., the only constant associated factor which Dr. Brush had found in the prevalence of human tuberculosis among a given people was its prevalence in the bovine race domesticated by that people. To establish this fact he first drew attention to the barbarous natives of Africa, among certain tribes of which tuberculosis was not known, and cattle were not domesticated; while among the tribes where tuberculosis prevailed, there also the meat and milk of the bovine race were used as food. Daniels had stated that along the coast of Africa tuberculosis was present among the people, while absent in the interior; and it had been further shown that the people on the coast used freely of cow's milk and drank the blood of the bullock, but in the interior cattle could not exist on account of a poisonous fly. Passing from the hot climate of Africa to the cold climate of Denmark, he found more than one cow to two inhabitants, and the death-rate from phthisis ranged between two and three per thousand; while in Iceland there was but one cow to four inhabitants, the dairy product was sold chiefly for the payment of debts, and was little used by the inhabitants, and phthisis was very rare. In St. Michael, of the Azores, the peasantry used scarcely any other milk than that of the goat or ass, and among them, according to Dr. Webster, phthisis was very rare. The Esquimaux also, who had no cows, were free from tuberculosis, while the disease was present among those who kept this domestic animal. Australia had been free from tuberculosis until the successful introduction of cattle, commencing about 1826. Previous importations of cattle had proven failures. The author believed that the death-rate from phthisis would go on increasing in that part of the world until the breeding of cattle should be properly regulated by law. Few countries enjoyed as great freedom from consumption as Switzerland, yet there the disease was much more common where the dairy product was most used. Madagascar's semi-civilized tribes had great herds of cattle, and made milk, meat, and rice their principal diet, and phthisis was also quite prevalent.

In Algiers phthisis existed only among those who used the products of the dairy, while the semi barbarous natives near them, who kept no cattle, were free from the disease. He believed that in Greece phthisis was rare among the natives, and in the town of Athens there were only five or six cows.

Men of scientific ability had sometimes, on visiting a strange country, found no phthisis among the inhabitants, while at a subsequent visit it was present, and they concluded they must have been mistaken in their first observation. But the probable explanation was that, since their first visit, cattle had been introduced. This was especially true with regard to India, where the cow was being gradually introduced by the English; yet among the natives who adhered to their religion the milk and meat of cattle was not used, and they had immunity from phthisis.

In the steppes of Russia, where there was absence of the bovine race, there was absence of tuberculosis among the people. In Quito, Ecuador, phthisis was absent, and what milk was used was first boiled. In certain parts of the plains of Ecuador, according to Professor Orton, the dairy cow existed, as did also phthisis. In some portions of Italy the death-rate from phthisis was extremely low, corresponding to the comparative absence of the dairy cow. In central and upper Egypt phthisis was decidedly uncommon, as were also cattle.

Taking into consideration all these facts, he thought there was little doubt that inbreeding in the bovine race was an important etiological factor of phthisis in the human race, not only in sowing the germ, but also in preventing its extinction. If cattle were to become extinguished, he thought the germ of tuberculosis would die out in the human race. The cow was the only animal which had been known to transmit tuberculosis to her offspring by inheritance. Yet he was fully aware that this statement would meet with considerable opposition, as many believed the disease was hereditary in the human race. This view, however, had not been proven.

Dr. Brush narrated an experiment made by him some months ago. He fed the tuberculous lungs of a cow dead of tuberculosis to some chickens, and soon one of the hens, which he afterward killed, showed tuberculosis of the laryngeal glands. He put her eggs under another hen, twenty-three of which developed fœtal chicks, but all were dead when the shells were broken. He took some of the eggs, which he had not used for setting, to the Carnegie Laboratory, and Dr. Grauer failed to find bacilli, but they were present in the lymphatic glands of the hen he had killed. Three of the hens fed on the tuberculous matter died, extremely emaciated, notwithstanding they had had plenty of food after having finished the tuberculous meat. One was burned, and the rooster, the last of the set, was stolen. There was nothing to account for the eggs failing to hatch.

He had found no evidence of tuberculosis developing in wild animals, nor would inbred cattle in which it prevailed be able to withstand the hardships of the wild state.

DR. HERMAN M. BIGGS expressed regret that Professor James Law, of Cornell, was not present to open the discussion, as had been expected. He had been greatly interested in Dr. Brush's paper, but must say that he could not accept his conclusions. Nothing was so unreliable as statistics, especially those of the kind quoted by the author. Even if the statistics given were reliable, they would not prove the conclusions arrived at. For instance, in the steppes of Russia, Hirsch had stated that, although tuberculosis was rare in that region, yet it did prevail to a certain extent. In Greenland, cows, sheep, and hogs were domesticated only in the southern portion, not in the northern, eastern, or western; yet Hirsch stated that in Greenland the mortality from phthisis was very large. According to the same authority, no country was more free from phthisis than Morocco, yet throughout that country there were considerable herds of cattle which resembled closely the Alderney breed. Then, in Egypt, phthisis was not very common except in the low countries, but there it was exceedingly common, and there was no evidence to show that inbred cattle were more numerous in those portions than in others. Again, reference had been made to the absence of phthisis in Quito; but while it is generally rare in the highlands of Western South America, especially in Peru, yet in the lowlands it was very common, while cattle were quite as numerous in the highlands as in the lowlands. Therefore he believed the author's statistics were unreliable. Besides, they left out other factors which influenced the development of tuberculosis. Before the Conquest, tuberculosis did not

exist at all among the inhabitants of Peru and Chili, but afterward, when the interior had been penetrated by Europeans, it became quite prevalent. In the Sandwich Islands the mortality from phthisis among the natives was now from twenty to twenty-five per cent., not because of inbreeding cattle, but because of the introduction of the disease by Europeans. The American Indians did not use inbred cattle, yet a large proportion of deaths among them was due to phthisis tuberculosis.

The theory advanced by the author left out of consideration other important factors. If tuberculosis were transmitted principally through the milk and meat of the cow, it would occur much more frequently in children, who were fed almost exclusively on milk; but, as a matter of fact, the disease increased with the advance of age. The fact that tuberculosis was more common where there were inbred cattle, could be better explained by the further fact that inbred cattle were most common among highly civilized people, who adopted customs tending to the development of tuberculosis. The things which had the chief influence in the development of phthisis were the food, the occupation, the clothing, the surroundings, etc., things entirely aside from the question of domesticating cattle. In a given locality it had been shown that those pursuing indoor occupations were most subject to phthisis. He thought the theory advanced would not at all account for the large mortality from phthisis among soldiers. It seemed to him irrational to ascribe phthisis in man to its existence in animals, when for its transmission it required the ingestion of the meat or milk of those animals. Tuberculosis acquired in this way should affect the alimentary canal rather than cause pulmonary tuberculosis. There were many other more probable ways for the transmission of tuberculosis, the principal one being the inhalation of dried sputum of tuberculous patients. Moreover, the portion of the tuberculous animal consumed by man usually did not contain the tubercle bacilli. The bacillus was rarely present in milk, except in mammary tuberculosis. The author had said that tuberculosis was most commonly found in the bovine race, but Dr. Biggs had found that more than sixty per cent. of hospital patients who reached the autopsy-table showed well-marked lesions of pulmonary tuberculosis.

Dr. Biggs closed his remarks by saying that the sputum was the chief agent for the transmission of tuberculosis, and while he believed that a larger number of cases occurred through infection from animals than was commonly supposed, yet he thought this number was very small compared with the total number of cases of pulmonary tuberculosis.

Dr. Forrest related a fact opposed to the view advanced by Dr. Brush, namely, that in the section of the South where he came from, the whites were almost entirely exempt from tuberculosis, while the colored people were much subject to it. The whites, however, were those who used beef and milk, while the negroes consumed very little of these articles, living mostly on pork and corn meal.

Dr. Crampton asked if there was a ready means of determining whether the meat and milk of the cow contained the tubercle bacillus, and whether heat would destroy liability to infection.

Dr. Agremonté said that in Port-au-Prince, Hayti, pulmonary tuberculosis was much more common among the colored people than among the whites, yet the latter alone obtained milk and beef; further, that the classes among whom it prevailed were accustomed to subject their meat (pork) to long cooking, which beyond doubt would kill the tubercle bacillus, as this microbe would not withstand a temperature of even 200° F. Again, he believed that tuberculosis was more common among domesticated swine than among cattle.

The President remarked that it was undoubtedly true other facts than the use of milk or flesh of cattle were necessary for the development of pulmonary tuberculosis, but that this aspect of the question did not belong properly to the subject treated of by the paper. Those other factors, as warmth, bad hygienic conditions, heredity, etc., were necessary before the bacillus tuberculosis could do its work.

Dr. Brush said that the work of Hirsch, quoted by Dr. Biggs with regard to phthisis among the tribes in the steppes of Russia and elsewhere, was simply a compilation. On the other hand, he had the authority of those acquainted in the steppes, including Medell and Daniel, that phthisis did not exist among those peoples.

He did not wish to be misunderstood. He did not hold that all cases of tuberculosis in man had their origin directly from the cow. He wished simply to say that wherever there were cows there was phthisis; that in the first place the disease began in the cow, and that if cattle were constantly absent from a country phthisis in the human race would cease to be. But where it had once become established, it would require some time probably for it to die out. He held, as Dr. Biggs and Dr. Loomis had expressed their views, that certain conditions were necessary for the development of the tubercle bacillus. At the same time the germ, and the disease to which it gave rise, must have a starting-point, which was in the cow. The fact that large numbers of soldiers died of phthisis, who received little milk and beef, did not invalidate his statement; tuberculosis existed among some of them to begin with, and spread rapidly on account of the unwholesome conditions to which soldiers were subjected. If men who used the milk and flesh of cattle were to contract tuberculosis as readily as small-pox or scarlet fever, few would now be living; yet it was from cattle that man in the first place got tuberculosis.

Dr. Porter inquired of the author how the breeding of cattle could be regulated to prevent phthisis.

Dr. Brush replied, by not inbreeding, and not breeding for milk.

Dr. Hadden, Chairman of the Section on Public Health and Hygiene, moved to take from the table certain resolutions recommending government control and prevention of yellow fever, and make them the subject of discussion at the first meeting in June. Carried.

Stated Meeting, May 2, 1889.

Alfred L. Loomis, M.D., President, in the Chair.

Dr. W. B. James opened the discussion with a paper entitled

THE RELATION OF THE TUBERCLE BACILLUS TO THE ETIOLOGY OF PULMONARY PHTHISIS,

in which he first traced the limitations of the term "tubercular" inflammation, and showed that evidence of its specific nature had been brought forward before the discovery of the tubercle bacillus. But while impressions of the infectious nature of the disease were not uncommon before 1882, it was not until that year that the specific microbe to which it owed its existence was discovered by Koch. It was with singular unanimity that the discovery of the tubercle bacillus as the cause of tubercular inflammation had been confirmed by subsequent investigators, so that to-day it was considered a fact well established in medical science that the presence of this microbe was absolutely necessary for the development of tubercular disease. The term pulmonary phthisis should be restricted to tubercular disease of the lungs. There were other conditions of the lungs, however, which during life one might not be able to distinguish from tubercular phthisis.

The question then arose whether the bacilli could alone produce phthisis, or whether contributory conditions were necessary for their growth? In other words, whether, for the acquisition of phthisis, some other element was necessary besides inoculation with the tubercular virus. Clinical experience showed that different individuals responded very differently to tuberculosis, as did also the same individual under different conditions. It was known that under treatment, for the most part climatic, some

cases of phthisis improved, and even entirely recovered. At the autopsies in the New York Hospital the past year, tubercular spots, more or less healed, were found in the lungs of more than half the bodies.

Whether a previous local lesion was necessary for the entrance of the tubercle bacillus was uncertain. Clinical observation and practical bacteriology went to show that the bacilli were capable of developing in healthy tissue. The number of bacilli or spores introduced, and their vitality, had an influence in the development of tuberculosis. Regarding the channel of infection in phthisis pulmonalis, it must be admitted that our knowledge of the lymphatics of the lungs was incomplete, yet it seemed probable infection might take place through them.

The author concluded with the statement that the evidence up to the present time seemed to indicate that the only factor necessary in all cases for the acquisition of pulmonary phthisis was the presence of the tubercle bacillus or its spores.

Dr. J. West Roosevelt continued the discussion with a paper on

THE RELATION OF THE TUBERCLE BACILLUS TO THE EARLY DIAGNOSIS AND TO THE PROGNOSIS OF PULMONARY PHTHISIS.

He began with the remark that the subject assigned him was one regarding which little need be said. He would not attempt to present new views. The first division of his subject was with regard to the value of the discovery of the bacillus tuberculosis in the sputum of patients in the question of early diagnosis of phthisis.

After stating business conditions which often rendered very important an early and positive diagnosis, he said that in phthisis there was often no tubercle so situated as to be connected directly with the air-passages, and consequently the absence of bacilli from the sputa could not be regarded as positive evidence that phthisis did not exist. It was indeed possible for extensive tubercular deposits to occur and yet no bacilli be discharged; it was also possible for so much bronchial discharge to take place that the bacilli might be overlooked in the large quantity of expectoration. Of course, the bacillus as positive evidence was invaluable. But the physician should not allow undue time to pass while waiting to find the bacillus, lest the patient lose his life before he made his diagnosis.

As seen in New York there was a number of cases of pulmonary phthisis in which the lesion until near the end seemed to consist simply of a deposit of tubercles, beginning usually in the upper lobes and gradually spreading and involving the lower lobe; with this tubercular deposit there was generally some pleurisy and bronchitis. In these cases there was not much tendency for the tubercles to break down early in the disease. There being practically no pulmonary consolidation, nothing at first but a few scattered tubercular nodules, the physical signs were of but little value. It was possible for such cases to progress very far, and yet give no distinctive physical signs. Unfortunately, for the same reason that the disease consisted of scattering tubercular nodules which did not break down early, the detection of tubercle bacilli was often impossible at the very time when its discovery would be of greatest value. It must be said that those cases presenting the greatest difficulty in diagnosis disregarding the bacillus, presented also the greatest difficulties in finding the bacillus. In many of them it was not to be found; the diagnosis must be made mainly from the history, and to a lesser degree from the physical signs.

As to the value of the bacillus in prognosis, he thought it could hardly be said to have any. Patients would be found going rapidly down, losing flesh and strength from day to day, whose expectoration contained but few bacilli; while, on the other hand, large numbers might be found in the sputa of those whose disease was advancing but slightly if at all. It was only a question of the freedom with which cheesy matter entered the bronchi. Dr. Roosevelt said he would venture beyond the bounds of his subject, and say that to administer antiseptic remedies in phthisis with the idea that it was rational treatment was ludicrous. In so terrible a disease the trial of any remedy not positively injurious might be justifiable, but one should not suppose for a moment that the administration of germicides could destroy the tubercle bacillus.

Dr. James Tyson, of Philadelphia, continued the discussion of the subject of the first paper. He could take no exception to the remarks of Dr. James. It was so generally acknowledged that the bacillus tuberculosis was responsible for tuberculosis, especially of pulmonary tuberculosis, that it seemed scarcely worth while to discuss the subject, yet it might be profitable to review the reasons for adopting any view of recent date. For a long time he could hardly believe that the bacillus tuberculosis could be responsible for pulmonary phthisis, but the evidence became too strong to longer doubt. Accepting this view of the etiology, he directed attention to some of the corollaries which grew out of it. First, tuberculosis was contagious, although only slightly so. As a recent observation going to prove this fact, he mentioned that of Flick, who found that Philadelphia houses in which consumption had occurred during the past twenty-five years were almost never isolated; that they were surrounded by other houses in which there was tuberculosis also, and in thirty-three per cent. of the houses in which there was pulmonary consumption there was more than one case. The second corollary was the communicability of tuberculosis by the alimentary canal.

As to inherited phthisis pulmonalis, we were forced to the explanation, in so-called hereditary cases, that transmission took place through the placenta. To say that it might be by impregnation of the ovum by the bacillus was pure speculation. As to the tenacity of life of the bacillus, it might live thirty days to six months.

Dr. H. M. Biggs thought experimental observations left not a particle of doubt of the causative relation of the tubercle bacillus to tuberculosis. There was one direct cause of tuberculosis, and only one, namely, the tubercle bacillus. That other factors had an influence could not be denied, but he believed their influence was only in diminishing tissue resistance. Without such factors as tubercular parentage, unfavorable hygienic conditions, depressed general vitality, ordinary exposure to germs of the disease might not lead to infection; but he believed that a sufficient dosage of the tubercle bacilli would cause the disease, no matter how healthy the individual, nor how favorable his surroundings. It was only a question of the introduction of a sufficient amount of the virus. Dr. Biggs laid stress on what he considered to be true, that in the question of heredity the disease itself was not transmitted, but rather only negative qualities, or weak organs, which made subsequent exposure to the virus particularly dangerous.

The conclusion could not be avoided that tuberculosis was a distinctly contagious disease, and consequently a distinctly preventable one. When these facts should be recognized, the great sanitary question would be how to restrict and prevent pulmonary tuberculosis. It would be necessary, in the first place, that all discharges of tubercular patients be disinfected, and that tubercular animals should be destroyed. The profession and the people should be impressed with the fact that tuberculosis could not spread except through the tubercle bacillus, derived from some other human or animal organism.

Dr. H. P. Loomis thought scarcely anything had been left to add to Dr. James' paper. He would repeat, however, that while in pulmonary phthisis there was, on the one hand, the tubercle bacillus, on the other we found what some chose to call predisposition, or lowered vitality, etc. This was a fact which should be borne in mind, although little definite was known regarding it. In a number of cases there was a hereditary predisposition to phthisis, while in others the condition favoring its development was acquired by habits of life, etc. He thought, however, there could be no question but what the tubercle

bacillus was the immediate cause of phthisis. In his experience at Bellevue Hospital there were, he thought, tubercular changes in at least sixty per cent. of all autopsies. He further stated that the clinical facts pertaining to phthisis had been accumulating many years, and one should be cautious in accepting laboratory researches which seemed to contradict those facts. The two must harmonize with each other.

Dr. Trudo showed specimens illustrating the growth of the tubercle bacillus on vegetables, and also in the lungs of animals after inoculation. The lesion in animals varied according to the quantity of the virus, place of inoculation, and environment.

Dr. William H. Thomson read a paper on

THE INFLUENCE OF THE MICROBE ON THE TREATMENT OF PULMONARY PHTHISIS.

He first discussed the subject historically. Among the attempts to cure phthisis by germicides, before the discovery of the tubercle bacillus by Koch, he mentioned the use of benzoate of soda in large quantities by inhalation, the idea being thereby to destroy the bacteria to which the tubercular process was believed to be due. After Koch's discovery of the bacillus tuberculosis, a new impetus was given this method of treatment, and trials were made with salicyn, iodoform, etc. At the International Medical Congress at Copenhagen the use of iodoform was freely discussed, some of the speakers preferring its administration internally, while others employed it in inhalation. The germicidal properties of iodoform were soon called in question; but notwithstanding the fact that experimenters had shown that the tubercle bacillus and other microbes would grow in it, this drug had held its place in antiseptic surgery, etc. It was not impossible that the products of decomposition of iodoform had some germicidal effects, yet Dr. Thomson had not been able to satisfy himself in its use in tubercular cases that it had any influence on the course of the disease. Injections of sulphuretted hydrogen per rectum had had no other effect in the hands of his house-physician than to cause some uncomfortable symptoms. Among other remedies which had been administered with the idea of obtaining their germicidal effect were tannin, acetate of lead, corrosive sublimate, creasote, etc., but no one of these could be proven to have an influence on the tubercular process. In experiments with them on animals, such doses could be employed as would cause poisoning and death of the animal without affecting the tubercle bacilli. The transportation of animals affected with tuberculosis to high altitudes had had no apparent influence on the disease. These facts seemed to show that the discovery of the specific parasite in tuberculosis would prove valueless, so far as treatment was concerned.

This, however, was no surprise to Dr. Thomson, for in other affections known to be infectious, as small-pox, scarlatina, and measles, he did not remember ever having seen a case aborted by medicine, antiseptic or otherwise. One might as well expect to stop the growth of weeds in a potato-field, without affecting the potatoes, by applying some substance to the soil. The weeds, when once they became implanted in the field, grew for the same reason that the potatoes grew, the pabulum for the one being the pabulum for the other, and to destroy the pabulum for the weeds would likewise starve the potatoes. The tubercular bacilli existed on the same nutriment which sustained the tissues of the body, and how could it be expected by drugs to change the nutriment of the one without changing the nutriment of the other? But was there no prospect, he asked, that Koch's great discovery might lead to some means whereby this most destructive disease could be combated? Some encouragement lay in the fact of the apparent interdependence of bacterial growths upon one another. He had probably been too much accustomed to regard the tubercle bacillus as a single entity which grew by itself, entirely independent of other conditions than its lodgement in a warm animal body. We were likely to forget that one micro-organism seemed to pave the way for another. Clinical experience demonstrated that pulmonary phthisis developed and advanced, rapidly or slowly, according to the activity or the non-activity of suppurative processes in the lungs. Hence, one of the plainest indications in treatment was to check suppuration. Another indication was to remove the pus as soon as formed; and a third, to prevent decomposition of the pus, for decomposing pus was as surely caustic to living tissue as were numerous chemical substances. He believed that some influence on these conditions was exerted by the use of creasote locally and by inhalation. While he had employed this remedy without much effect on the progress of many cases, yet on his records it showed a larger proportion of favorable results than any other single agent he had tried.

A second indication, which he would mention briefly, was the possible limitation of the tubercular process by promoting resistance of the tissues of the body to infection. Of the thousands who were exposed all their lives to the entrance of the tubercle bacillus into the body, only a few afforded favorable conditions for its growth.

Dr. Thomson stated, incidentally, that a good subject for investigation was the external physical characters of phthisical patients. Such a study might reveal a constitutional proclivity to infection. He mentioned some of those characteristics which distinguished phthisical patients from those suffering from chronic bronchitis.

Dr. Louis Waldstein continued the discussion on the subject of Dr. Roosevelt's paper. He said he could only give some examples in proof of the correctness of Dr. Roosevelt's conclusions. The presence of the bacillus tuberculosis was of the greatest importance as a positive sign of tubercular disease; but we could not assume with certainty that such disease did not exist when the bacillus could not be found in the expectoration. A young man was taken with a cough, began to emaciate, but various physicians pronounced his trouble of no importance, viewing his cough as the result of an irritable throat. Later on, expectoration set in, and became profuse, but he was treated for bronchitis. One physician had repeatedly examined the sputa, with negative results. He was sent to Dr. Waldstein, who, on examination of the chest, was unable to come to any conclusion regarding the gravity of the disease. He examined the sputa at intervals, and the fourth or fifth time detected tubercle bacilli in large numbers, which settled the question of diagnosis. After several months distinct physical signs of phthisis were present at the apex of the lung. In other cases repeated examinations of the sputa for bacilli had been negative, notwithstanding physical signs of grave and progressive disease.

In regard to prognosis, he cited the case of a young, healthy-looking man, who, during business hours, had an attack of severe pulmonary hemorrhage, which was repeated twice within twenty-four hours. Three or four weeks before, a careful examination for life insurance had given no indication of pulmonary disease; yet microscopical examination of the expectoration, mixed with blood, showed large numbers of tubercle bacilli. The man was sent away, recovered, and repeated examinations of the chest and sputum, after his return, were quite negative. Thus, we must subscribe to the assertion of Dr. Roosevelt, that the presence or absence of the bacillus tuberculosis was valueless with regard to the prognosis of the case.

Dr. B. F. Westbrook, of Brooklyn, thought the gentlemen who had discussed the question of etiology had somewhat overstated their case. He did not think the tubercle bacillus was to be regarded as the only cause of tuberculosis. To be sure, the gentlemen who had taken part in the discussion had not stated it in exactly that way, but Dr. Biggs had come very near it. The causation in the animal organic world was very complex. That fact had been recognized two thousand years ago by Aristotle, who wrote a treatise on the subject, showing that different causes might be combined to produce a

given effect. While, according to the knowledge of the day, the tubercle bacillus was the only original exciting cause of pulmonary phthisis, yet it was not the only cause aside from the exciting. To say that it was the exciting cause was stating only one factor in the problem of causation. There were many others, and he thought that practically the others were the more important, for the tubercle bacillus could not be excluded, while perhaps some of the other causes, if they were only thoroughly investigated, might be excluded.

With regard to the value of the tubercle bacillus as positive evidence in diagnosis, he had never seen a case in which it could be found by the microscopist when the physical signs taken with the history did not afford sufficient evidence without it. But there were some cases in which examination of the sputum had been of some aid to him in determining whether primary tubercular pleurisy existed.

With regard to prognosis, if he had a case of pulmonary disease presenting signs of consolidation and excavation, with long-continued cough and purulent expectoration, and did not find tubercle bacilli in the copious expectoration, he would give a favorable prognosis; he would conclude that it was a case ordinarily known as chronic interstitial pneumonia, and that the prognosis was good. If in the course of such a case tubercle bacilli appeared, it would be a bad sign. Its presence would usually be accompanied by fever. Aside from that, he would regard the number of bacilli as of no importance.

Treatment based on the discovery of the bacillus tuberculosis, aside from cleanliness, had been valueless, if not harmful. Cleanliness and fortifying the constitution of the patient to withstand the disease were indicated; not poisons for the destruction of the bacilli.

Dr. F. P. Kinnicutt said he could only confirm the statements of Drs. Roosevelt and Thomson with regard to influencing the life of the tubercle bacilli by germicides. Antiseptics were only of value in the way of cleanliness and removing morbid secretions. They might be of value in stimulating the nutritive processes, but not in exerting a direct influence on the bacilli. Such, he thought, was the explanation of the benefit derived from creasote. It had often seemed to him that the principal benefit in pulmonary phthisis came from attention to details and strict supervision over the patient's daily life.

SECTION ON THEORY AND PRACTICE OF MEDICINE.

R. C. M. Page, M.D., Chairman.

Stated Meeting, April 16, 1889.

Dr. E. A. Bracklow read the report of a

CASE OF PURPURA HÆMORRHAGICA,

occurring in a young lad, with exhibition of the patient.

Dr. M. Allen Starr read a report on

THE USE OF SIMULO IN THE TREATMENT OF EPILEPSY.

Dr. E. D. Fisher said that he had had no practical experience with the use of the drug, as its costliness was such that he had not felt justified in trying it in dispensary practice. His attention had been first directed to it by Dr. White's article in *The Lancet*, in March, 1888, referred to in the paper. It would certainly be a great advantage, he thought, if we could get any agent which would at all take the place of the bromides in those cases of epilepsy in which the use of the latter was attended with bad effects. The tincture of simulo, so far as employed, would seem at least to have no bad effects. Dr. Starr had expressed no opinion as to its mode of action in cases of epilepsy, and he thought some information on this point was desirable, as nothing had as yet, so far as he knew, been published regarding it. On the whole, simulo seemed worthy of a further trial. In some of the cases reported it appeared to do well in connection with the bromides, and he would like to inquire if Dr. Starr had ever used it in this way.

Dr. Landen Carter Gray said that he could only agree with Dr. Starr as to the uselessness of simulo in epilepsy. He had tried it in several cases (at least four or five), both alone and in combination, and he had obtained from it no results except such as one could get in almost any case of epilepsy by changing the drugs employed. This was merely a temporary effect, and the same could be obtained by any one of almost a hundred other agents. He had therefore discontinued the employment of simulo, as it had, in his hands, proved so nearly useless as not to afford sufficient encouragement to give it a more extended trial.

Dr. Starr said, in answer to Dr. Fisher's question, that he had not tried simulo in combination with the bromides.

Dr. F. W. Jackson read a paper (see p. 510) on

THE SIGNIFICANCE OF THE CREPITANT RÂLE.

Dr. J. West Roosevelt said that he had been correctly quoted by the author of the paper, but since the publication of the article referred to he had seen reason to modify his views somewhat. Authors are very apt to speak rather wildly on this subject, some claiming that the crepitant râle was produced only in the air-vesicles, some only in the pleura, and others that it might be in either. It was a matter of importance to understand just what was meant by crepitant râle. If Laennec's definition was to be accepted, that it consists of a series of sharp, crackling sounds heard at the end of inspiration, and apparently near the ear, it must be admitted that the crepitant râle is met with in phthisis, in severe bronchitis, in pneumonia, in dry pleurisy, and in œdema of the lungs. He explained that he was referring to the kind of râle which is heard only in puffs, and is of a high pitch, the true crepitant râle. As to the cause of the production of this râle, he did not feel prepared to express an opinion. There could be no doubt, he went on to say, that there was a distinct movement of the air in the vesicles. In pneumonia we talked of the solidified lung as not moving at all; but either the lung did move or else the pleura was immovable. A solidified lung could be expanded to some extent, since the smaller bronchi occupied a considerable space. He would be inclined to deny, therefore, that the crepitant râle cannot be produced in the air-vesicles. There could be no question, however, that the râle was also heard in pleurisy, and hence it was necessary to depend on other signs in order to differentiate between pneumonia and pleurisy. As to Dr. Leaming's teachings, he thought it was a great pity that so much of what was of absolute value should be mixed up with that which was not proven. Frequently in the dead-house he had found the pleura perfectly healthy in cases in which the crepitant râle had been distinctly heard a few hours before. Yet, at the same time, he believed that he was perfectly right in attributing the greater number of crepitant râles to the pleura. As to Germain Sée's suggestion, to look for the râle at the level of the seat of pain, he had repeatedly found at autopsies that there was no disease whatever in the immediate vicinity of the location where the pain had been experienced by the patient.

Dr. W. W. Van Valzah said that in his experience the crepitant râle was to be found not only in pneumonia, but also in pleurisy, in œdema of the lung, and in œdema of the pleura; and he did not, therefore, consider it pathognomonic of pneumonia. It was largely moist in character. As a rule, the pleuritic crepitant râle could be heard over a much less extended surface than the pneumonic.

The Chairman, Dr. Page, said that he had always taught that the true crepitant râle was produced, as Laennec believed, only in the lung, and that analogous sounds heard in the pleura and in various pathological conditions should not be so designated.

Dr. Roosevelt asked if such analogous sounds could be distinguished by the ear from the true crepitant râle,

and Dr. Page replied that they might not present any difference whatever to the ear, but differed only in the mode of their production.

Dr. Jackson, in bringing the discussion to a close, said that it was greatly to be regretted that we were not in possession of a more accurate definition of the crepitant râle than had as yet been attained. Among his students he was in the habit of using the definition of Dr. Roosevelt, that it is a very fine râle which is heard at the end of inspiration. It was not, however, altogether satisfactory to himself, and Walshe taught that the râle was heard at the beginning of inspiration.

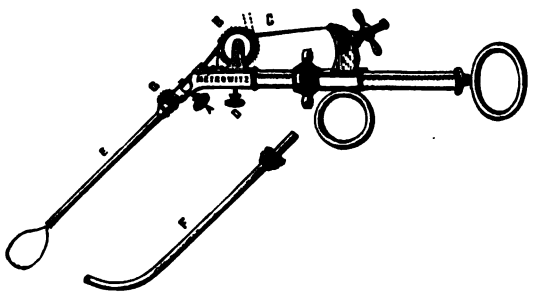
New Instruments.

A NEW POLYPUS SNARE.

By GEORGE D. HALL, M.D.,

GALVESTON, TEXAS.

The body of the snare, which is made of steel, thus rendering it very strong, can be detached from the cannula E at D. The wire having been placed around the growth is tightened by means of the stop-screw. If the operation is to be quickly done the milled nut is turned and the growth severed as usual. If it is desirable to cut the growth very slowly, as is often the case in hypertrophies of the posterior ends of the turbinated bones, the growth being engaged, the wire-holding screw A is tightened and the wire cut a little behind the ratchet-wheel B;



then bent to prevent slipping, the body is detached from the cannula, the screw A loosened, the wire is drawn home, as slowly as may please the operator, by means of the ratchet B.

The advantage which I think this instrument possesses over others lies in the fact that the cannula part of the instrument is in itself a complete snare, and being lighter and shorter than any other, does not require the patient to hold it up like other and heavier snares, while its own weight in position does not make it burdensome.

April 6, 1889.

A MODIFED ALLIS ETHER INHALER.

By JOSEPH W. EDDY, M.D.,

OSWEGO, N. Y.

After using a number of kinds of ether inhalers, I have come to the conclusion that the Allis inhaler is the best;

C, C, top, which comes off; *A*, leather jacket; *B*, rubber face-piece.

there being no valves to get out of order, and the construction is simple; but I found that where it was needed for a number of patients, as in a railroad accident, it generally became too dirty in a short time to use, owing to the presence of saliva and vomited matter, and taking it apart to clean and put in a new canton flannel bandage was very tedious and trying to the hands, especially in removing and putting on the rubber cap. In my modification the canton flannel is not threaded through between the bars, but slipped over as the top comes off, and then in place of the rubber cap over the bars I use a black patent-leather jacket, over one end of which is slipped a rubber face-piece, which has the end going over the patent-leather jacket distended by a metal ring or band so that there is no trouble in introducing it over the jacket. Surgeons will find that this inhaler can be taken apart and the bandage changed in a few moments.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 27 to May 4, 1889.

Forwood, W. H., Surgeon Medical Department, Fort Snelling, Minn. Based on surgeon's certificate of disability, leave of absence for one month, with permission to leave the limits of the Department, is granted. Par. 1, S. O. 35, Headquarters Department of Dakota, St. Paul, Minn., April 8, 1889.

Borden, William C., Captain and Assistant Surgeon U. S. Army. Relieved from duty at Fort Ringgold, Texas, and ordered to report to the commanding officer at San Antonio, Texas, for duty at that post. Par. 7, S. O. 100, A. G. O., May 1, 1889.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 4, 1889:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	4	1
Scarlet fever	268	33
Cerebro-spinal meningitis	3	3
Measles	126	7
Diphtheria	149	57
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

Rheumatismal Metatarsal Osteo-periostitis.—The apparently unrecognized, or but little recognized, disease of infantrymen is written of in an interesting article in the *Revue Générale de Clinique et de Therapeutique*, by Dr. Charles Eloy. It may be considered as an œdema localized at the head of the two or three metatarsal bones of the centre of the foot, with an accompanying osteo-periostitis. The cases on record number 20, 8 having been reported by Pauzat in 1887, 11 by Poulet, 1888, and one by Eloy. Of the 19 cases of Pauzat and Poulet, 2 were old soldiers. In all of the cases the symptoms came on after marching. In all the cases there were two cardinal symptoms—painful œdema and periostitis. The œdema was first manifested, after one or more long marches, by a swelling limited to the level of the dorsal face of the two or three intermediate metatarsals, and sometimes invaded the root of the toes or effaced the tendinous projection of the extensors. It is of medium hardness, depressible under the finger, and accompanied by slight elevation of the temperature. The pain accompanying it is not spontaneous, but is provoked by pressure

and by movements. There is a very manifest arthralgia of the metatarso-phalangal joints when a toe is seized with a pair of forceps and repeatedly flexed. The localized œdema and the pain are the signs of the beginning of the affection, and characterize the first period. After some time periostosis begins. The finger, and sometimes the eyes, of the observer can detect swelling of the metatarsals. This periostosis may appear as early as the fourth day, but usually not until the twelfth or fifteenth day. Whether it comes on early or late, the periostosis persists for several weeks, or even months after the disappearance of the œdema, the diminution of the pain, and the return of the tendinous prominences to their normal form. These phenomena characterize the second period —the osteoplastic phase. There are two views as to the pathogenesis of this affection. On the one hand it is claimed that it is a traumatic periostitis; on the other, it is thought to be an osteo-periostitis of rheumatismal origin, and consequently the local manifestation of a specific affection. Pauzat excludes all constitutional influence. His patients were young men, aged twenty-one or twenty-two, robust, vigorous, with well-formed feet, but unfitted by previous occupation for long marches. Fatigue, then, seems to be a predisposing cause. Seven of the eight cases reported by Pauzat were those of soldiers recently enlisted. But it is a curious fact that the affection was never bilateral; one foot only was affected, and one as often as the other. Is it not possible, however, that men that have not learned the whole art of walking perfectly use one foot more than the other—put more strain on one foot? Some foot-ball players, for example, can kick with only one foot, while others use each foot with equal facility. Can the shoes be responsible for the affection? In view of the small number of soldiers affected this does not seem probable; but it would be interesting to have some statistics from the Spanish army, in which, we believe, the soldiers use sandals on the march. The prognosis of the affection is serious, according to Pauzat; good, according to Poulet. Pauzat's unfavorable opinion is based on the fact that the osteo-periostitis places the patient out of actual service for a considerable time. Poulet bases his prognosis on the fact that the malady does not prevent the patient from entering the service again. The treatment of the affection, according to Eloy, consists in rest, elevation and immobilization of the foot, and topical applications and compression. Topical revulsives, such as the iodides, should be used in the osteoplastic stage of the disease.—*The Journal of the American Medical Association.*

Blood-poisoning in Medical Students.—It is reported that several fatal cases of blood-poisoning have occurred recently among the Paris medical students practising in the dissecting-room of the École Pratique. It appears that, in consequence of a decree of the Municipal Council, surviving relatives, who formerly paid a fee of seven francs to have the bodies of those dying in hospitals, can now receive them gratis. The dearth of subjects which is the result of this change has led to greater putrefaction than usual, and an arrangement is now being made for the sending of bodies from Lyons and other large cities.—*Medical Recorder.*

The Danger of Reporting Strange Cases.—We referred not long ago to a case of delivery on the rail, reported by Dr. Osler, and now we have to chronicle the sad sequel to this case as related by Dr. Osler himself, in the *Montreal Medical Journal.* The unfortunate man writes: "A few days ago I received an urgent summons to come at once to an address at the northern part of the town. On arrival I found my *confrère* looking very tired and distressed after a night with a primipara. He greeted me with the information that one child had been born, but that he did not know what to do about the second, as he believed there was hour-glass contraction of the uterus. I assured him that our course of action was clear; we sent at once for an obstetrician. I had difficulty in convincing him that I was not a professor of the art, but he persisted that my reputation was associated in some way with obstetrics, and brought up that northwest case. What I have suffered on account of that baby; to be jeered at by the French journal, to be called by the editor of The Medical Record a narrator of funny stories, to be referred to by my friends as Munchausen—these things have been hard to bear, but on the strength of that case to develop a consulting practice in obstetrics, is indeed a warning. Hereafter I shall stick to my last."

Early Twin Embryos.—Twin pregnancies are of great interest both to the obstetrician and to the embryologist. True twins are developed from one yelk, and it has long been known that the embryonic appendages of one embryo may cut off those of the other from the placenta, and thus give rise to remarkable malefrmations. The placenta is common in all one-yelk twins. The simultaneous development of twins from two ova is also an interesting subject. At a meeting of the Berlin Obstetrical and Gynecological Society, Dr. Gottschalk exhibited a pair of twins aborted at the second month. They showed very marked differences in their degrees of development. The mother was thirty-one years of age, weakly and anæmic; her youngest and second child was aged two years. She aborted eight weeks after the cessation of the catamenia, from no particular cause. The larger ovum was expelled into the vagina without aid; the lesser had to be detached from the fundus with the finger. Both ova were fresh and uninjured. The bigger was just under two inches broad and over three long; the smaller an inch long and four-fifths of an inch broad. The extremities of the larger embryo were completely developed, those of the smaller formed mere buds. The relative sizes of the placentæ corresponded to the development of the ova. Dr. Gottschalk did not consider that he had to do with a case of superfœtation. He traced the lesser ovum to the same period of ovulation as its brother, considering, however, that it was fertilized somewhat later.—*British Medical Journal.*

A Sure Remedy against Sea-sickness has at last been discovered by a physician of Vienna, Franz Heller by name. It consists simply in keeping the body level by following the motions of the vessel, bending the right knee as the vessel rises to that side, and then the left as the motions are reversed. It might be somewhat tedious, not to say tiresome, to follow out this brilliant suggestion during a voyage from New York to Liverpool.

A Novel Cure of Tapeworm.—A writer in *La Clinica Navarra* relates the case of a man who had received a stab-wound in the abdomen involving the intestine. The injured portion of the gut prolapsed through the wound. The surgeon who was called to attend the sufferer noticed something issuing from the opening in the intestine, and recognized on closer inspection several segments of a tapeworm. He succeeded in extracting the worm entire, which measured over sixteen feet in length. The intestine was then sutured and returned to the abdominal cavity, and the man made a good recovery.

Boyish Appetite.—The relations between appetite and digestion is in general a fairly definite one. At the same time it must be allowed that this rule is largely modified by exceptions. Many persons are subject to morbid cravings to eat, which food cannot satisfy; and most of us know something of the appetite of idleness, of habit, or of nervous disturbance—the latter bearing a suggestive likeness to the desire for stimulants or the fragrant weed, taken to relieve mental depression. Apart from such considerations, however, there are obvious variations in the degree of normal appetite in different individuals and at different periods of life. The man of sedentary habits cannot expect to compete with one who spends a life of movement out of doors. The man and the woman differ, so do the younger and the elder, and in a notable

degree, the boy and the man. The vigorous appetite of boyhood is virtually a synonym of health. A rate of daily consumption which would in most men be gluttony is in young growing lads almost too common to attract notice. The explanation is not difficult when we take into account two chief conditions of existence at this age—the growth going on in every organ and tissue, and a very liberal allowance of active bodily exertion. Under the circumstances a sparing rule of diet would be unnatural and injurious. There is, of course, a limit even in childhood which it is trite to say is often and wrongly exceeded. There is no age, however, at which this form of excess is so pardonable. Whatever the surplus of food taken, most of the self-indulgent youngsters have been provided by nature with a power of disposal which may largely be relied upon to correct its consequences. Measures of restriction are most wise when they are used to regulate rather the wholesomeness of food and the times of eating than the absolute quantity consumed. It is at a later stage that we may require to apply strictly the familiar rule that one should eat to live and not live to eat. A degree of apparent Philistinism in the matter of wholesome food and drink is in the young both usual and judicious.—*The Lancet.*

A Genito-urinary Surgeon of this city states that he has been successfully treating deaf-mutes with sounds.

Enucleation of the Eyeball.—Dr. Coppez, of St. John's Hospital, Brussels, publishes in *La Clinique* the details of a method of enucleation which he considers to be easier and simpler than the methods of Bonnet and of Tillaux now in use. The patient having been anæsthetized and the eyelids separated by a speculum, a thread is passed transversely through the cornea by means of a curved needle; the ends of the thread are knotted and the loop held in the left hand. By traction on this loop the eye is drawn slightly forward, and with a curved scissors the conjunctiva is divided close to the corneal edge. The subconjunctival tissue is then torn through, and the tendons of the recti muscles come into view and are divided, next the tendons of the oblique muscles, and finally the optic nerve. Dr. Coppez claims for his operation that it may be practised with fewer instruments—a curved needle, scissors, and a speculum; that the optic nerve may be divided more directly and at a greater depth in the orbit, which, in the case of malignant tumors, is of great importance; and that the consequent hemorrhage is less considerable than in the ordinary operations. The only objection to it, he thinks, is that the globe might be rendered flaccid by the escape of the aqueous humor through the needle-holes; but that is of little importance.—*The Lancet.*

Cupping-glasses in Depressed Fracture of the Skull.—Dr. Piper reports the case of a child, seven years of age, who had received an injury resulting in a depressed fracture of the left parietal bone. The treatment consisted in the application of a cupping-glass over the seat of the fracture, by means of which the depressed portion of bone was brought into its proper position. —*Medical Register.*

Maggots in the Uterus.—Dr. J. F. Haines reports the following case in *The Lancet* of January 5, 1889. Some months ago I was called to see Mrs. P——, who stated that she had had "a miscarriage" three days previously, and was now suffering from considerable pain. There was an intensely fetid discharge, and, on making an examination, I was surprised to discover a number of maggots in the vagina. I injected a solution of carbolic acid, which, however, had but little effect, only a few maggots coming away with the return of the fluid. I then used as an injection a solution of perchloride of mercury, which killed and brought away a very large quantity of them. The patient now expressed herself as considerably relieved, and, there being no urgent symptoms, I prescribed a mixture containing tincture of opium and liquid extract of ergot. Next day I repeated the injection of the perchloride, and on the following day a mass about the size of a small orange was expelled, which was riddled with holes, and contained a number of dead maggots. I was unable to satisfy myself as to whether it contained any fœtal structure or not. After this the patient steadily improved, and made a good recovery.

Poisoning by Citrate of Caffeine.—Mr. T. Geraty reports the following unusual case in *The Lancet* of February 2, 1889. At 9 A.M., before breakfast, a lady suffering from migraine took a dessertspoonful (equal to 200 grains) of pure citrate of caffeine in mistake for the granular effervescing form of the drug. I saw the patient immediately after the accident; the only complaint she then made was as to the nauseating taste. I encouraged her to eat a little porridge before having an emetic. As soon as the porridge was eaten, faintness and nausea came on; and a quarter of an hour after the reception of the poison there was semi-unconsciousness, grave depression, extreme pallor, all the muscles completely relaxed, and a decided inclination to sleep; pulse slow, soft, and very compressible; respiration slow and sighing. The treatment adopted was an early emetic (one-twelfth of a grain of apomorphia), which acted at once and very completely, small quantities of brandy, the recumbent position, and warmth. I may say there was a well-marked rigor about an hour after the caffeine was taken. Consciousness was recovered about an hour and a half after emesis, and the faintness passed gradually away.

Treatment of Tonsillitis in the Early Stages.—For a case of quinsy, seen in the first twenty-four hours, Sajous recommends a gargle of a teaspoonful each of ammoniated tincture of guiac and milk. The gargle is to be used every three hours and then swallowed. After the third or fourth dose the patient is usually much relieved. If the remedy cause diarrhœa it should be reduced to half a drachm of the guiac with one drachm of milk.

The Dose of Salicin.—According to Dr. McLagan (*The Lancet*), salicin must be given in large doses in rheumatism, from twenty to forty grains every hour, until there is decided evidence of its action. Generally before an ounce is given improvement has taken place, and as the symptoms decline the dose may be diminished.

Juvenile Inebriety in Austria.—The temperance of Austrian women has long been proverbial; but, if the accounts recently published respecting the intemperance of boys and girls in that country are reliable, we fear that Austria will not long continue to sustain its former good character for feminine sobriety. So serious and widespread has inebriety been of recent years among school children that the Vienna School Board have, though hitherto ineffectually, been making strenuous efforts for the prohibition of the sale of intoxicating drinks to children. The Board has just resolved to invoke the intervention of the Government, and a bill is to be laid before Parliament during the present session to prohibit the selling of intoxicants to boys and girls under fifteen years of age. So alarming is the present state of matters that the appearance of a boy at school in a state of drunkenness is by no means a rare sight. During the winter poor children are often sent to school with only a glass of the cheapest spirits for breakfast, partly to allay hunger and partly to "keep out the cold"—that venerable delusion which still lingers in England. Slav children of the tender age of five and six years are so "seasoned" to alcohol from infancy by the administration of small quantities in milk that these youthful scholars can take a liberal dram without showing any symptoms of intoxication.—*British Medical Journal*, November 17, 1888.

Now that the college clinics have ceased for the season the younger practitioner will have an occasional chance for a stray patient.

Original Articles.

"IS MORE CONSERVATISM DESIRABLE IN THE TREATMENT OF THE JOINT DISEASES OF CHILDREN?"[1]

BY A. B. JUDSON, M.D.,

ORTHOPEDIC SURGEON TO THE OUT-PATIENT DEPARTMENT OF THE NEW YORK HOSPITAL.

THE established method of treating the so-called tubercular diseases of the joints is by opening the joint and excising or scraping the diseased bone. This method, called when it was new the conservative method, superseded amputation, and was indeed a great advance. It has occurred to me to present to you a few considerations which favor a still further advance in conservatism, as applied to the treatment of these diseased joints in children. Will it do, for instance, to withhold the knife altogether? If we answer in the affirmative we differ from the active operating surgeon of the present day, who views with indifference the opening of the cavity of a joint, or that of the abdomen, thorax, cranium, or vertebral canal. Taking a general view of operative surgery, this most attractive and popular branch of our science, the most interesting feature is the sudden relief of pain or the rapid transition from desperate peril to safety which sometimes follows a bold operation. As Sheridan turned disaster into victory in the Shenandoah Valley, so the bold surgeon makes his incursion into the valley of the shadow of death and returns with the trophy of life and health. But it may well be asked whether operating on a joint affected with chronic osteitis is ever followed by speedy restoration of health and function. Is it not true that the patient is so long in making a recovery that the operation always fails as an instance of brilliant and successful surgery? If the wound of operation or the sinus would only close, and the patient be well in a month or three months or six months, it might be said that the operation is justifiable and praiseworthy. But how many such patients linger a year, two years, three years, or longer, after the operation? And when finally they recover it becomes evident that the only effect of the operation, if the patient escapes with his life, has been to forestall needed mechanical treatment through overweening belief in the sufficiency of the knife, and perhaps to needlessly shorten the limb or give undue mobility to the joint.

It may be said that such a miscarriage of surgery is the result of a failure to remove all the diseased tissue. Must we, then, in the treatment of these cases, proceed as if we were dealing with a malignant affection? The great number of scarred but healthy cripples who have recovered without competent surgical attention excludes the thought of malignancy, and even indicates that in every uncomplicated case a point will certainly be reached when the destructive is replaced by a reparative process.

It is not to be denied that it would be well if, in some instances, the diseased parts could be entirely removed. But is this ever done, or can it be done? Theoretically their removal is desirable in the very earliest stage of the disease. But the subacute focus in which the disease has its origin lies hidden in some unknown part of the cancellous tissue, we know not how long, before it produces symptoms. It may even be resolved before its presence is recognized. And when the symptoms declare themselves, it is not clear at first which bone of those forming the joint is the seat of disease, and when that point is settled we are at a loss to determine the number and location of the foci. The upshot of these baffling conditions is that the operation is necessarily postponed until the foci break down into pus and an abscess forms, and in this stage the exploring surgeon usually exposes a great quantity of diseased tissue which gave no external indication of its presence. He finds that thorough removal of all that is diseased, with nothing left in the extensive wound but healthy tissue, is an impossibility. He not only has difficulty in deciding between healthy and unaffected bone, but he also runs the deplorable risk of extirpating portions which are granulating and cicatrizing. He knows not how many foci not yet broken down lie beyond the reach of his excavations. In view of these embarrassments, it is not strange that the expectation of a rapid recovery after operation in the so-called third stage is always disappointed.

There is one consideration which probably has weight in the minds of those who have to decide the question of operating or not, and that is the dread of visceral degeneration—the amyloid liver and kidney—as the result of long-continued suppuration. Doubtless many an operation has been undertaken in cases where an immediate successful result has been out of the question, simply for the purpose of diminishing the flow of pus. This source of danger I have had no reason to take into consideration in practice. In the few patients who have had degeneration of the liver and kidneys, this condition has seemed to be an expression of a vice of constitution of which the pernicious course of the joint disease was but another expression. I may add that I have seen reason to believe that serious disease of these organs, especially of the kidneys, occurring in the class of cases under consideration, is not always or generally fatal.

In general terms, the performance of severe operations on the skeleton of a child is to be avoided on the ground that the patient is growing. All the parts and functions should be preserved rather than sacrificed or abridged in the slightest degree. The smallest piece of tissue or the least remnant or fragment of an ability is to be preserved and cherished, because it will not only have the growth which belongs to it in common with the rest of the body, but a growth stimulated by the effort which nature always makes in such circumstances to supply a deficiency. An adult may demand a rapid recovery at the risk of loss because his time is valuable, but growing children have time to spare. If they are out of school for a while they catch up quickly when they return to their books. If a boy is so equipped that he is free from pain and can be out-of-doors, he is not much cast down or impeded by the presence of a diseased or even a suppurating joint. An unopened abscess or a discharging sinus is often looked upon by the family friends of the patient as a most distressing and dangerous complication, the one feature of the case which calls for sympathy and strenuous treatment, when it is in reality but a secondary and unimportant incident. The sinus, no matter how wide and deep, will permanently close when the diseased bone which is the source of the pus is cicatrized, and not before, and the diseased bone cannot be successfully treated by impracticable efforts at extirpation, still less by attempting to treat the abscess or sinus. When it is proposed to see whether the progress of the disease cannot be cut short by oper-

[1] Read before the Orange Mountain Medical Society, April 12, 1889.

ating on either the bone or the soft parts, at that very moment, in all probability, the bone is on the way to spontaneous recovery to be followed by permanent closure of the sinuses. The insertion of drainage-tubes, the injection of antiseptic fluids, and the other resources of minor surgery will but cause discomfort—they cannot hasten the time when disintegration ceases and repair begins.

Are we, then, powerless in a case of this kind? By no means. If we can rightly settle ourselves in the opinion that chronic osteitis of the joints in children is an affection the duration of which cannot and need not be abruptly shortened, we are in a more favorable position to inquire what we can do to promote and stimulate the natural process of repair and provide for the greatest possible ultimate symmetry and ability. There is, however, another particular in which we will perhaps have to free our minds from a preconceived notion. I refer to the expectation of seeing our patients recover without impairment of form and function. Patients do not pass the ordeal of chronic osteitis of the joints with normal symmetry and ability. I do not here refer to those rare cases in which the osteitic focus is resolved in its early stage.

Having thus cleared the ground, so to speak, by admitting that these cases cannot be cured, in the popular meaning of that term, and that such a cure as can be obtained is to be sought by relying on the slow but sure processes of natural repair and not by operating, we are in a position to construct or outline a plan of treatment as best we may. In the general management, which is a most important part of the treatment of a child affected with chronic joint disease, I have found it difficult to keep the parents from acting on a false notion of the severity of the disease and the peril of the patient. It is not easy to convince the parent of a child who wears a splint and has purulent collections and discharges that such a child should be allowed to run about at will and to eat all kinds of food. But, practically, a child in this condition should be incited to activity. He should almost be driven from his bed and from a habit of invalidism. If the "running sores" are viewed with apprehension by the adults of the family the child will suffer in imagination, but if they are made light of he will soon learn, what is the fact, that they are painless and readily tolerate disturbance and even violence, and they will not then prevent him from enjoying life with his play-fellows and fortifying his appetite and general condition with fresh air and the wholesome activities of childhood. Such a child should, as a rule, be an "office patient;" if treated at a hospital he should be an out-patient. A child leading such a life would expect, and should have, the diet of healthy children. There will be days when he will be overcome by lassitude and nights when he will lose part of his sleep through pain. During these periods, which diminish in length and frequency as the case approaches recovery, the patient will be less active, the regulation of the diet will call for special attention, and judicious medication will be required. When the transient depression has passed there is all the more reason for encouraging a return to activity.

But many of these patients will be unable to be active unless we restore to them the power of locomotion of which they are temporarily deprived by the disablement of a limb. The first point which claims practical attention when local treatment is begun is the necessity of fixing the diseased joint. If this can be done a great deal of pain and discomfort is arrested, and not only is pain arrested but we thus apply to the inflamed joint the most widely recognized antiphlogistic, arrest of function, just as we forbid the use of an inflamed eye or arrest the motion of the inflamed pleura by surrounding the chest with a strip of adhesive plaster. And when the joint is securely fixed it becomes evident that the patient is not only benefited locally but also generally, because now he can move about without disturbance of the joint and is able to climb the stairs in-doors and make the wished-for excursions out-of-doors.

Thus far we have made no distinction between the joints of the upper and those of the lower extremity, but it will be necessary to make this distinction because we all know that the former are much less frequently and less seriously affected by osteitis than the latter. For instance, we have no shoulder disease comparable in frequency and destructiveness with hip-disease. White-swelling of the knee has, from the beginning of surgery, been a reproach, but there is no affection of such frequency and severity in the elbow. I believe the difference depends on difference in mechanical environment, and chiefly on the fact that the upper extremity, being pendent, is exempt from the pressure and concussion which, from the nature of the case, fall to the lot of the lower extremity in standing and locomotion.

A glance at the statistics of orthopedic institutions reveals some interesting facts bearing on this question. From the last annual reports of two such charities in New York City it appears that in a single year 577 patients were treated for disease in the hip, 181 in the knee, 6 in the shoulder, and 8 in the elbow, making an aggregate of 758 patients with disease in the large joints of the lower, and only 14 with disease in those of the upper extremity. The disproportion is not so extreme as it appears to be at the first view, because doubtless many cases of disease of the shoulder and elbow are retained in general hospitals; but it will probably be agreed that in the great majority of cases of chronic articular osteitis the affection is found in the lower extremity. The first and most obvious inference is that the occurrence of the incipient osteitic focus is rare in the upper and common in the lower extremity. But is this a reasonable inference? Is not the more remote inference more likely to be correct that foci occurring in the cancellous tissue of the upper limb are resolved at an early stage and before recognition, because they are, from the nature of the case, exempt from the violence which in the lower limb forbids early resolution. The practical lesson to be drawn is the necessity of imitating in the lower the mechanical environment of the upper limb. The lower extremity should be made a pendent member by some form of crutch, axillary or perineal, from the earliest recognition of the disease till its resolution. In this way we not only relieve and prevent pain, but we also apply to the inflamed joint the most widely recognized antiphlogistic arrest of function—and what function of bone and joint in the lower extremity is more arduous and exacting than that of enduring the weight of the body, standing and in locomotion? And when the painful limb is relieved from this burden it becomes evident that the patient is not only benefited locally but also generally, because he is now able without apprehension to do with considerable ability his share of out-door sports.

I will not on this occasion intrude on your attention the details of mechanical treatment, because they cannot be well appreciated in the absence of clinical demonstration, and also because it is in the power of every practitioner to apply the principles which I have referred to and which are detailed in many publications.

While it would be difficult to find a case of chronic articular osteitis in which mechanical treatment would not meet with general approval, the majority of surgeons probably choose to combine with it some form of operative treatment. For my part I would make mechanical treatment an essential element in the management of every such case, recognizing the possible value of the knife, but not seeing, or expecting to see in ordinary practice, cases which would be benefited by its use. I have not cited cases and have not tried to make a formal argument, but have sought to present in an unstudied way the impressions and convictions which practice and observation have led me to in the hope of turning your thoughts in the same direction.

4 East Twenty-fifth Street.

THE ETIOLOGY AND TREATMENT OF PNEUMONIC FEVER.[1]

By JOSEPH T. SMITH, M.D.,

VISITING PHYSICIAN TO BAY VIEW ASYLUM, BALTIMORE, MD.

It is with much hesitation that we bring before you the subject of pneumonia; in our medical journals it holds a prominent place at this time, and the various societies throughout the country, one after another, have called it up for discussion. The Clinical Society has thought this an apportune time for her members to be heard, and that in some form the disease, so familiar to every practitioner, though in many of its aspects still shrouded in mystery, should be brought to their attention, in order that those who feel disposed may express their views. After the experience of last year, during which 671 persons died of pneumonia in this city, it has seemed all the more needful that the disease and its results should be again examined; and if in the review we shall find nothing new, we shall at least be strengthened in the belief that we are doing the very best that can be done. Dr. Daniel Drake, in his "Diseases of the Interior Valley of North America," says in the edition of 1854: "As pleuro-pneumonia may occur in every part of our valley from the latitude of 48° down to 24°, as it is often engrafted on our typhus fever, and quite as often complicated with a malarial diathesis, it follows that we should regard it as one of our most momentous diseases." That it is still a most momentous disease we need go no further for evidence than our own good city of Baltimore. If we review the past ten years, from January, 1879, to January, 1889, we find that 5,016 of our population have died from pneumonia, an average of a little more than 500 a year; during that period there were only six weeks in which no deaths were reported, namely, August, 1879, 1880, 1881; September, 1881, and July, 1887, 1888. The greatest number of deaths in any one month was 119, in March, 1888, average thermometer, 36°; the smallest, 9, in August, 1879, average thermometer, 76°, and August, 1883, average thermometer, 73°. The death-rate last year (1888) was nearly 100 greater than in any year for the past ten, and nearly 200 greater than the year preceding.

As the whole field cannot be covered, we desire to note but two portions of it, as those about which the chief interest centres at the present day, namely, its etiology and treatment. I think we may agree with Dr. Sternberg, that "acute pneumonia is now generally regarded, by the leading clinical authorities and pathologists in this country and in Europe, as a specific infectious disease." We may also, I think, agree with Professor Flint, that "each of these names (croupous pneumonia of the German writers, and fibrinous pneumonia of the French writers) is incorrect, and they all imply that the disease is a purely local inflammation, whereas there are sufficient grounds for regarding it as an essential fever. A more appropriate name is, therefore, Pneumonic Fever." We find, then, the pneumonitis of our fathers no longer a simple inflammation of the lungs, but an essential fever, infectious in its nature.

The causative agent expending its energies upon the lungs, as that of typhoid fever upon Peyer's patches, or that of malarial fever upon the red blood-corpuscles, seems all the more certain if we note the experiments upon dogs, in which the supposed agent injected beneath the skin in moderate doses failed to give any result, but intrathoracic infection always caused a frank, fibrinous pneumonia which was rarely fatal.

If the lessons of the present day teach us anything in regard to pneumonia, it is that we must look upon it as an essential, infectious fever. In looking for the cause of this fever, one does not search far until he meets with those who tell us that it is a germ, or at least that in every case certain species are always present in the diseased tissue of the lungs. The field, in so far as pneumonia is concerned, has been well studied; Friedländer, Talamon, Sée, Klein, Sternberg, and a host of others, have, after diligent search, placed in our hands to-day a something—the micrococcus Pasteuri—which, in the words of Dr. Sternberg in summing up the results of experiments, "in very susceptible animals (mouse, rabbit) invades the blood and quickly causes death by septicæmia; when injected through the thoracic walls in less susceptible animals (dog, sheep), or in an attenuated form in the rabbit, gives rise to the local lesions which characterize fibrinous pneumonia." It is needless at this time for us to consider this organism or theorize as to how it acts in producing pneumonic fever; doubtless you have all read the able discussion of it in the published paper of Dr. Sternberg, read before the Medical Society of the State of New York on the 6th of February of the present year.

If it shall be shown at some future day that the micrococcus Pasteuri is the cause of the fever, still other causes, or, more correctly speaking, other influences, must be brought to bear upon the individual before pneumonic fever will show itself. These latter, from the practitioner's point of view, require more care and attention, that the direct cause, if any such, be yet found.

We note but two of the indirect causes, if the term is allowed, as those most worthy of attention. It is everywhere recognized that the disease is most prevalent in the winter and spring months; the past ten years' experience here amply confirms the fact that pneumonic fever is then most active. That the disease is always present with us is shown from the fact that in the decade noted, only six weeks elapsed in which no deaths occurred, though doubtless cases existed even then. With striking uniformity the largest death-rate in each year was from November to May. These are our coldest months, but cold itself is not causative, for we do not find a very low temperature necessarily causing an increased death-rate; thus in January, February, March, 1888, with a temperature respectively of 29°, 35°, and 36°, the death-rate was 87, 100, and 119; while in the same months in 1881, with a corresponding temperature of 28°, 34°, and 42°, the death-rate was 73, 42, and 35. Dr. Thomas Darling, in his article on the etiology of pneumonia, shows in striking contrast the outbreaks of pneumonic fever among the workmen on the Croton Aqueduct—the epidemic as it showed itself among those under the most wretched hygienic surroundings, as in Shaft 23, and those more abundantly supplied with fresh air and better hygienic surroundings, as in Shafts 24 and 20. The Italians fared the best of them, he says. "The shanties for the Italians were not as well built as for other workmen, and to this I attribute partly the good results obtained. It was possible to see the daylight from the inside in any portion of the building, so that there was no lack of fresh air." In speaking of the epidemic in Shaft 23, he says: "This epidemic occurred in one room of a large shanty in which eighty men slept, forty during the day and forty during the night. There were but two windows, and these were never open. The odor was that of a menagerie. On the tenth day I had the room emptied, the sides and ceiling whitewashed, the bedclothes washed, and mattresses taken out into the sunlight and as much as possible washed, the windows opened, and the floor sprinkled with chloride of lime. Then the epidemic as such ceased abruptly." Thus it is more than probable that the causative agent is more active in the months noted, not so much on account of the low temperature, as that during the colder months we get less fresh air, keep our houses more or less poorly ventilated, and in our endeavor to shut out the cold we shut in these causes which tend to impair our vital resistance. This brings us to the second influence at work in causing pneumonic fever, namely, anything which impairs the vital resistance of the individual will make him a fitting subject; thus alcoholic excesses, prolonged exposure to cold—especially if combined, as it so often is, with insufficient nourishment—living in close, ill-ventilated dwellings, etc., are known to be the forerunners in very many cases of pneumonic fever.

[1] Read before the Clinical Society of Maryland, April 19, 1889.

We agree with Dr. Sternberg, in part at least, when he says: "The constant presence of this micrococcus in the buccal secretions of healthy persons indicates that some other factor is required for the development of an attack of pneumonia; and it seems probable that this other factor acts by reducing the vital resisting power of the pulmonary tissues, and thus making them vulnerable to the attacks of the microbes. The germ being always present, auto-infection is liable to occur when, from alcoholism, sewer-gas poisoning, crowd poisoning, or any other depressing agency, the vitality of the tissues is reduced below the resisting point."

It would seem, then, as though pneumonic fever were caused by a specific organism, the micrococcus Pasteuri; that it is most frequent in the winter and spring months, because then we surround our bodies with those causes which tend most to impair our vital resistance, and when that reaches a sufficiently low point, the active causative agent invades the lungs and sets in motion the series of phenomena we call pneumonic fever.

In considering the treatment of pneumonic fever, in its first stage, we are at once confronted with the question, "Shall we bleed our patients?" It is now admitted by all that blood-letting is only to be resorted to, if at all, at the outset of the disease, and after that time it is worse than useless. Flint has considered it very advantageous, and lays down this rule for its use: "High fever, the pulse more or less resisting compression; or, in other words, arterial tension and a robust constitution." In the discussion which followed a paper upon the subject of blood-letting, at the last meeting of the State Faculty, Drs. Williams and Chew related cases showing the marked good results which followed the prompt and judicious use of this measure. A careful study of the experiences of those most qualified to judge will show that the profession is looking upon blood-letting with more favor each year, and is disposed to assign to it a high place for good, if properly used; and in few diseases are its good effects more brilliant than in that now under consideration. Its usefulness is narrowly limited, and like all our powerful agencies it must be used with the discretion such always demand. As Professor Chew remarks regarding it: "We are now returning to the rational system of practice."

Upon the full establishment of the disease and the onset of the fever, a second question presses for an answer: "Shall the elevation of temperature be controlled—when and how?" This opens up such a broad field, and one so filled with combatants—it opens up that vast subject the treatment of fever, which in itself would demand a whole evening to give even an outline view—that we may be pardoned if we but glance at the question. We endorse the opinions of Dr. Whittaker, as expressed by him when discussing the subject at the meeting of the American Medical Association, 1888: "The bacteria," he says, "are sensitive to heat; 170° F. attenuates the bacteria of Fränkel in from twenty-four to forty-eight hours." This corresponds pretty well with the clinical history of a case of pneumonia. The fever may be the very agent destroying the disease. It has been observed that those were the most favorable cases in which the temperature was most pronounced. Danger is not on the part of the fever, but on the part of the heart, and the question is whether it is not the best plan of treatment to sustain the heart—let the fever alone, be content with small doses of antipyrine or antifebrin to do away with any evil effects of high temperature." Dr. Shattuck, at the same time, said: "During the past the influence of temperature in pneumonia has been overrated." He has discarded the systematic use of antipyretics in this disease. This, then, if an essential fever, should be treated as such, in so far at least as the elevated temperature is concerned; and so long as it does not exceed 103° F. no harm is being done, and, as a rule, antipyretics should be withheld. Opium to relieve pain and secure rest; counter-irritation of a mild kind; possibly the careful use of tartar emetic; the tonic effects of quinia, etc., are points in the treatment so familiar as hardly to call for mention.

In the second stage our chief concern is in regard to the heart, and we will continually seek from the pulse information as to whether or not our patient shall be overcome by the exhaustion incident to the disease. As has been said, "resolution will be sure to begin and continue, if the life of the patient be sufficiently prolonged."

If there is one danger more than another that is apt to beset our path, here it is—that in our anxiety to keep down the temperature we give it undue attention, and the first, often faint, indications of heart failure escape us. We should not wait until the signs of the oncoming asthenia are well marked, but at the very first indication of heart failure we should apply our remedies. We need to bear constantly in mind that "danger is not on the part of the fever, but on the part of the heart."

It is also needful that we lay more and more emphasis on the value of fresh air and the thorough ventilation of the sick-room. The difficulties here are great, as we all know. It is hard to make our patients fully alive to the importance of fresh air in such a disease; and do we not have ourselves to blame at times in that, while we are concerned with the increased temperature and asthenia, we fail to call to our efficient aid that too common ally, fresh air.

Dr. Gouverneur Smith, of New York, in a discussion of this subject, puts all else in the background and brings "fresh air" to the front. We should ring the words into our patients' ears with no uncertain sound, so that they may realize that it is as much an element in the treatment as any of our therapeutical means. The writer above quoted says: "It is more than ordinary ventilation that is required in such cases; what is needed is a persistent, systematic attention to a constant change of air in the apartment of the sick by night and by day, each hour, each minute, each second. . . . Attention in the line above indicated should be excessive." The less breathing-space the patient has, the more particular should we be that the portion of the lung that is active should receive a full, free amount of air loaded to its utmost with oxygen. The sick-room should thus not only be well ventilated, but people, gas-lights, and every possible source of vitiation of the atmosphere should be most carefully excluded. At the present day we believe that a patient well nourished is in a better condition to combat disease than one poorly nourished, and thus we find it needful to keep the nutrition of the tissues in the greatest state of perfection. Thus we believe that when we have, in suitable cases, rarely to be found, drawn blood by cups or the lancet; have used our antipyretics only when the evil effects of a high temperature show themselves; have brought our remedies actively to bear upon the heart when the first faint symptoms of failure in the power of that organ are observed, remembering that "danger is on the part of the heart;" seen to it that "fresh air," in the fullest meaning of the term, is supplied without a moment's intermission; the nutrition at all times well maintained, and our drug stores called upon to furnish drugs to meet the indications of pain, etc., as they arise, we have done the very best for our patients that we can with our present knowledge.

Two points call for mention in conclusion. One is: Have we made advances in our treatment? It does not become us to enter a field at present occupied by two such able men as Dr. Hartshorne and Dr. Osler; the statements of the two are familiar to all of you. We believe with Dr. Osler that "Dr. Hartshorne's statement, that the mortality of pneumonia to-day is, under similar circumstances, more than twice as great as it was forty years ago, is not borne out." A second point is: How shall we account for the seeming epidemic influence of the disease, such as was witnessed here last year? It is due, among other causes, to the fact, possibly, that we have an accumulation of material suitable for the activity of the microbe, as we find in the case of the poison of small-pox, which, in spite of our precautions, will now and then find sufficient unprotected material upon which it can feed and produce an epidemic of the disease.

ANOTHER VIEW OF MATERNAL IMPRESSIONS.

By R. OSGOOD MASON, M.D.,

NEW YORK.

In the *Medical Age*, March 11, 1889, appears a communication upon the above subject, which, notwithstanding some crudities and a great deal of dogmatism, contains the gist of the argument against maternal impressions so sharply put as to call for a moment's consideration.

The writer characterizes the supposition that birthmarks may be influenced by maternal impressions as "the old woman's idea," and, in opposition to those who have written in favor of such a supposition, he feels "forced, in the vindication of science," to break his silence.

The following unqualified assertions are then made: "It is as utterly impossible for a mother to mark her child *in utero* as it is for a fowl to mark the young that is in the eggs under her." "When we advocate such an unscientific reasoning as the possibility of a mother transmitting nervous impressions to her young *in utero*, we show to the world that we believe in ghosts, and not in the progressive science of our age." "Stop, gentlemen, and think for a moment that there is not the least nerve-communication between the mother and her child."

The argument, fairly presented, is that, since no nerve-filaments have been demonstrated in the cord or placenta directly connecting mother and child, therefore no nervous connection exists, and no nervous influence or effect can be transferred from one to the other, any more than from the hen to the eggs in the nest beneath her.

The care for the honor of science which animates the bosom of this author is doubtless shared in some degree by others who have contributed in various ways to the literature of this subject, possibly even by some who favor the "unscientific" view which he deprecates.

As an example of those who may fairly be supposed to have had the honor of science at heart, and yet have ventured to entertain views upon this subject at variance with those of our author, I would mention the distinguished professor of physiology, the late honored president of the College of Physicians and Surgeons of New York, Dr. John C. Dalton. In the chapter on the placenta, in his treatise on "Human Physiology," he says: "There is now little room to doubt that various deformities and deficiencies of the fœtus, conformably to popular belief, do really originate, in certain cases, from nervous impressions, such as fear, disgust, or anger, experienced by the mother." From the well-known effect of various emotions, or of nervous shock upon the circulation, as shown in the face, the brain, the uterus, and, as might be added, upon the milk and other secretions, as well us upon the functions of excretion and evacuation, Dr. Dalton argues that as the fœtal circulation is dependent to a great degree upon the maternal circulation, and as the nutrition of the fœtus is provided for wholly by the placenta, nervous impressions or nervous shocks received by the mother may be reasonably supposed to produce the effects referred to through the placental system of circulation and nutrition. This is a method of conveying the effect of nervous impression to the fœtus not possible in the case of the hen and the egg in the nest.

No intelligent observer supposes that deficiencies, deformities, or other birthmarks are produced in any other way than through the medium of the circulation. Nor do they see any "witch footprints" nor any other miraculous effects in connection with this process, but only the operation of natural law.

However, since Dr. Dalton recorded the views above quoted, the rôle in physiological action played by nervous impressions has been found to be much extended; many new facts have been observed, and many alleged facts formerly rejected or looked upon with suspicion are now either fully received or at least respectfully considered. This same nervous influence which produces the blush or the pallor of the face, the cerebral congestion, the sudden check of menstrual flow, or change in the nutrition of the fœtus, is now believed by many reputable and scientific men to be able also, in certain exceptional cases and under certain peculiar conditions, to produce definite limited local effects, such as marks and discolorations, upon particular portions of the body, known as stigmata, the oozing of blood from the unwounded skin, the removal of local paralyses, and curing of other functional disorders. The investigations and experiments of Liébault, Bernheim, Forel, and others have established a series of remarkable facts bearing upon this subject; not that many of these facts were new, but they had simply shared the fate of new facts generally in every age. Sometimes it has been religion, sometimes philosophy, and sometimes science which has been their conservative opponent; but whichever it may at any particular time have been, if the new facts did not tally with the received theories of that time —so much the worse for the facts.

In regard to the series of facts above referred to, a theory has been devised which science can accept, and upon the respectability of the theory they are accredited. By these facts it is established that mental impressions received from some other person, or from some strongly dominant idea, are capable of so affecting the vaso-motor system as to produce the remarkable effects of vesication, stigmatism, and bloody exudations—effects, which, a few years ago, were relegated by science to believers in ghosts and seers of "witch footprints," but which are now received and respected as facts. As in these cases the effect is produced upon the person who receives the impressions, objection might still be raised to applying the same reasoning to effects produced by maternal impressions upon the fœtus *in utero*. The following question might then properly be considered, namely, Can nervous or any personal or vital influence extend beyond the limit of actual nerve-supply?

The alleged facts bearing upon this subject occupy the same relation to science now that the received facts in relation to the effect of mental impressions or powerful emotions upon the vaso-motor system did ten years ago; they are, for the most part, relegated to the believers in ghosts and seers of "witch footprints." Nevertheless, numerous and well-authenticated facts bearing upon this subject exist, and while this is not the place to recount them, the more special questions to which they relate may be briefly stated. The following may serve as examples:

Is it a fact that, independent of obvious conditions, such as cleanliness, health, beauty, intelligence, or the influence of sex, many persons of sensitive nervous organization coming in contact with, or even into the presence of, some persons, entire strangers, are agreeably and pleasantly affected, while the presence of others is disagreeable or even painful?

Is it true that such close sympathy or relationship may exist between two persons that, being separated from each other by such a distance as to render perception by ordinary means impossible, still some violent mental emotion, or sense of danger, or injury received by one is perceived by the other at the same moment?

Is it true that this same relationship may be so powerful that at the moment of the death of one of the related persons such an effect is produced upon the other that a visual perception of the dying one is distinctly received?

If facts exist bearing affirmatively upon these questions, and consequently upon the theory that impressions may be received from sources entirely beyond the limit of nerve-supply, it bears an important relation to the subject of the effect of maternal impressions upon the fœtus; and, taken in connection with the established fact of the effect produced by mental impressions upon the vaso-motor system, furnishes reasonable ground for an argument in favor of the theory that birthmarks may be caused by maternal impressions.

No conclusive argument for or against the theory at present exists; but the great number of birthmarks which are referred to maternal impressions, and the very remarkable and pertinent circumstances attending many of them,

point strongly to some relation between them other than simple coincidence.

So it seems neither modest, useful, nor scientific to simply assert that a relation of cause and effect does or does not exist; nor for those who believe, on the one hand, or those who do not believe, on the other hand, to bandy epithets. The question undoubtedly possesses scientific interest; therefore let the well-authenticated, pertinent facts be faithfully reported, and then let the fair deduction which "the progressive science of our age" will surely make be patiently awaited.

SANITARY ADVANTAGES OF SALT LAKE CITY.

By H. D. NILES, M.D.,

SALT LAKE CITY, U. T.

THE sanitary advantages of Salt Lake City, to which the writer has ventured to call the attention of the profession, are as follows:

1. A distinctly local climate, apparently possessing to a marked degree the popular requirements of a high-altitude resort.

2. Unexcelled salt-water bathing, the peculiarities of which may indicate unusual remedial virtues.

3. Hot, warm, and cold sulphur springs, of alleged marvellous curative properties.

Such a combination of natural remedial agents in one city is unique, and it is hoped that the following brief description of them may not be devoid of interest, and perhaps may lead to their further investigation by the medical profession which may establish their true value. Until quite recently, owing to circumstances which need not be explained, the investigations of the health-seeker, as well as those of other visitors, have received but little encouragement from the residents of this city. They have rather repelled anything that to them looked like an interference with their exclusiveness. Fortunately these conditions no longer exist.

The writer of the present article will attempt, briefly and fairly, to present some of the statistical data and theoretical grounds for believing that Salt Lake City is justly entitled to a high rank as a sanatorium, leaving for a future article the confirmatory evidence of clinical observation, and the less valuable testimony of the health-seeker himself.

A high-altitude resort should possess the greatest possible dryness and equability, an elevation of from 3,500 to 8,000 feet, the greatest number of sunshiny days during the year, in which the invalid may enjoy out-door life, a comparative freedom from wind- and sand-storms, a proper temperature, and certain other qualifications not of a purely climatological character. An attempt has been made to name the climatic factors in the order of their comparative importance.

The tables A, B, and C are compiled from the reports of the United States Signal Service and embrace a period of observations from 1874 to 1884, inclusive. From 1863 to 1874 observations were taken at Fort Douglass.

Dryness.—First in importance is dryness of the air as indicated inversely by the relative humidity. Salt Lake City's air averages 44.6 per cent. relative humidity, and consequently lacks 55.4 per cent. of saturation, showing a greater absorption capacity than any place in the United States where observations have been taken.

Recent investigations have tended to strengthen the prevailing opinion of the great value of the absorptive and aseptic qualities peculiar to dry air in the treatment of pulmonary diseases. It is a well-known fact that warmth and moisture favor decomposition and the generation of micro-organisms, and lessen the vapor transpiration. Exactly the opposite may be said of cold, dry air. It destroys or retards germ-life, in and out of the lungs, and increases the amount of moisture exhaled. The moisture thus exhaled may also serve as a vehicle for the removal of effete matter, wasted tissue, and germs of disease.

Dr. Denison, whose original researches have thrown so much light upon our knowledge of high-altitude climates, suggests a very ingenious method for calculating the excess of moisture exhaled in a cool, dry air over that in a warm, moist air. In this calculation Glaisher's estimate of the weight of vapor in grains, in air of a given temperature, is adopted; and it is assumed that the dew-point in exhaled air is 94° F., and that it is saturated. Apply this method of calculation to the air of Salt Lake City, Denver, and Los Angeles in the case of a good-sized man, who, we will suppose, breathes twenty times a minute and thirty inches per breath on an average, and note the great excess of moisture exhaled daily in the two former places with a dry, cool air, over the latter with a warm, moist air.

	Salt Lake City.	Denver.	Los Angeles.
Average temperature	49.5°	49.4°	60.4°
Weight of vapor at saturation for given temperature in grains (Glaisher)	4.0	4.0	6.94
Average relative humidity	0.44	0.512	0.682
Cubic feet of air breathed in twenty-four hours	500	500	500
Weight of vapor inhaled (grains)	880	1,024	2,367
Weight of vapor exhaled, dew-point 94°, saturation being 16.69 grains per cubic foot (grains)	8,345	8,345	8,345
Vapor exhaled more than inhaled	7,465	7,321	5,978

Excess of Salt Lake City over Los Angeles in vapor exhaled, 3 ozs. 47 grs.
" " Denver " " " " " 2 " 383 "
" " Salt Lake City " Denver " " " " 144 "

But if allowance be made for one-fifth greater amount of air breathed (the air being one-fifth rarefied), Salt Lake's excess in transpiration over Los Angeles would reach over four ounces daily.

In noting the remarkable aseptic and absorptive properties of the air, the question is suggested, May not these qualities have a favorable influence on our surgery?

From 1863 until the establishment of a station at this point observations were taken at Fort Douglass, in the suburbs of this city, and five hundred feet higher than the present station. During this time the average relative humidity was 43.5 per cent. This fact would seem to indicate that on the mountain-sides, near the city, the air might be even dryer than in town.

Atmospheric pressure.—In regard to altitude, Salt Lake possesses the advantage of being located immediately at the foot of a range of mountains, enabling the health-seeker to select any altitude of from four thousand to eight thousand feet above the sea level, as may be best suited to his particular case. Or he may vary it as the progress of his case demands, and still be near enough to the city and lake to enjoy all of their advantages. In those rare cases where a still higher altitude is advisable there are desirable places, but at a greater distance from the city.

Number of clear and fair days.—In Table A it will be noticed that Salt Lake has an average of two hundred and seventy-seven clear or fair days in the year. This is a large proportion, but not equal to some other places of about the same or higher altitude. It is believed, however, that after making a fair allowance for the number of so-called clear or fair days, when sand- and wind-storms prevent the enjoyment of out-door life at these places, the balance would be in favor of this city. It should be explained that of the remaining eighty-eight days classed as cloudy there are very few in which the sun does not shine a part of the day. Old residents estimate that on an average there are not five days in the year in which the sun does not shine.

Wind.—Tables A and C give an idea of the relatively small number of miles travelled by the wind during the year at this place, and the average velocity and direction of the winds for each month. It should be added, that there is a comparative freedom from high winds, and an

entire absence of cyclones and hurricanes. High winds, like variability, have hitherto been regarded as necessary evils of high and very dry places; in other words, that places sufficiently sheltered by mountains to be protected by the wind, could not be very dry. The absence of these objectionable features in Salt Lake is, therefore, worthy of especial mention.

Temperature.—With an annual average mean of 49.5°, and an annual daily range of 18.6°, this city has an exceptionally cool, equable climate. Possessing the advantages of seasonal changes in the temperature, these changes are so gradual and the air so dry that neither the cold of winter nor the heat of summer produces the unpleasant effects that they otherwise might. On the sides of the snow-capped mountains, in close and convenient proximity to the city, are places where the invalid may find both altitude and coolness during the months of July and August, should an average temperature of 74° be deemed too warm. Between 1874 and 1885 the average coldest winter day was but 6° below zero; and the average warmest day in summer but 95° above zero. Between 1863 and 1874 the average lowest temperature was 4° above zero. Dr. Hamilton compares the average annual range of this city with a few other prominent cities as follows (time 1863 to 1874):

Montreal	140°
New York City	114°
Denver	126°
St. Louis	133°
Chicago	132°
Salt Lake	93½°

A very rare, if not unique, feature in the climate of Salt Lake is its remarkable equability, as shown by the mean daily range of 18.6°. Equability has been regarded as belonging exclusively to low, moist localities, and "variability as a distinguishing attribute of all high and very dry places." Mr. Brice says: "It becomes a matter for careful study to determine wherein lies the happy mean between dry climates with great daily range, and moist climates with small daily range of temperature." Other authorities are equally positive in the conclusion that equability is incompatible with great dryness. The reply to the climato-therapeutist who has demanded dryness and equability combined has been, you ask that which is impossible.

In the possession of this combination it would appear that Salt Lake City is able to offer that which is likely to prove equally satisfactory to the climato-therapeutist and the health-seeker who has been driven from other high resorts on account of their variability.

The mountain protection on the east, and the moderating influence of two thousand five hundred square miles of salt water on the west, undoubtedly have much to do in producing this distinctly local climate.

Diathermancy and Ozone.—It is generally believed that diathermancy of the air increases with the altitude, and that ozone is most abundant in sea-air, and the air of mountainous regions. The writer knows of no local conditions that would lead one to conclude that the atmosphere of Salt Lake was an exception to the rule in this respect.

To sum up, then, I believe that it is fair to conclude that in points of dryness of the air, equability of temperature, comparative freedom from wind and sand storms, and elevation (four thousand three hundred feet, and higher places in convenient proximity) Salt Lake City stands without a parallel. No other city has a more favorable temperature or a greater number of bright, beautiful days in which a patient may safely and pleasantly enjoy out-door life. These conclusions being true, Salt Lake City possesses the nearest approach to an ideal high-altitude climate at present available.

Other qualifications not of purely climatological character.—The location of the city and its soil are favorable for perfect drainage. The city drinking-water is from the mountains, and of the limestone variety. A recent analysis shows a minimum amount of organic matter. Artesian water is used to some extent, and can be procured at a depth of from ninety to one hundred feet.

Concerning the diet, it should be said that, in addition to all the articles of food procurable in any Eastern city, there is an abundance of wild game and fish (brook trout and others). As an evidence of the excellence of the fruit and vegetables, it may be said they bring a higher price in the San Francisco market than the California products. A not unimportant attribute of this health resort

is the fact that with the opportunities afforded by the great number of beautiful days are the inducements offered by Salt Lake City to live as much as possible in the open air. With its grand and picturesque scenery, its fine drives, shaded avenues, beautiful lawns, luxuriant foliage, etc., no city possesses a greater number and variety of attractions to invite the health-seeker into the open air.

Bathing in the Great Salt Lake.—Analysis of the water:

	Grains.
Sodium chloridi	11.735
Calcium carbonatis	.016
Calcium sulphatis	.073
Magnesia sulphatis	1.123
Magnesia chloridi	.843
Water	86.210

Percentage of solids 13.790, against about two per cent. in ordinary sea-water. The specific gravity is 1.170. The water is entirely free from odor. It is possible that the quality and large proportion of saline matter may have a sanatory significance. The only natural body of water having as high a specific gravity is the Dead Sea.

The calmness of the surface, the buoyancy of the water, and the fine beach all combine to render bathing and swimming in the lake easy and pleasant exercise for the average invalid, and free from many of the difficulties and dangers attending ordinary surf-bathing. No living thing inhabits the waters of the lake, an advantage that will be appreciated by the sensitive and timid.

Within the past year and a half elegant, spacious buildings have been erected at the different resorts, and every effort is being made to comfortably accommodate the rapidly increasing number of bathers; so that, with the exception of the peculiarities mentioned, this bathing resort does not materially differ from that of any first-class ocean resort.

The Sulphur Springs.—It is not generally known that thermal springs exist in the vicinity of Salt Lake, owing to the fact that they never have been advertised. However, a number of very excellent sulphur springs are found within the limits of the city. These vary in temperature, from extreme cold to 130° F. They all contain a small quantity of free carbonic acid, and a large amount of sulphuretted hydrogen gas. An analysis shows each pint of the water to contain solid constituents as follows:

	Grains.
Sodium chloridi	60.40
Potassium sulphatis	1.41
Magnesia sulphatis	3.10
Sodium sulphatis	18.73
Sodium carbonatis	1.94
Silica boratis	.18
Potassium chloridi	1.12
Magnesia chloridi	6.28
Calcium chloridi	1.02
Calcium carbonatis	3.13
Magnesia carbonatis	.77
Alumina boratis	15.50

It is hoped that the above analysis may furnish some light as to what may be expected of these springs, therapeutically. The bathing accommodations and means of transit to and from the springs are not what they should be, nor what springs of such apparent excellence deserve. Notwithstanding these inconveniences, these springs are largely patronized, and marvellous stories are told of their efficacy in rheumatic, syphilitic, and skin diseases.

Those who would try this wonderful and unique trio of "Nature's own remedies," should know, however, that Salt Lake City, as a health-resort, is not free from objections. With a population of 35,000 people this city has no underground system of sewerage.

The streets are not paved and the city is poorly lighted. The supply of water under the present system is inadequate. There are no regular resort hotels. Where there need be neither dust nor mud, this city is not entirely free from either. The sanitary condition of the city is not what it should be. Fortunately, all of these are remediable faults. Indeed arrangements have already been perfected for a more abundant supply of water and a complete sewerage system; and it may safely be predicted that where Nature has been so lavish in bestowing her favors, man will not long neglect the little left for him to do, and in the near future the health-seeker will find in Salt Lake not only everything that contributes to the health and comfort of the invalid, but a most beautiful city in which to live.

Clinical Department.

UNITY OR DUALITY OF SYPHILIS.

By GEORGE J. MONROE, M.D.,
LOUISVILLE, KY.

ARE syphilis and chancroid, or hard and soft chancre, one and the same disease? All authors and teachers, at the present time, say they are not. All experimentation and symptoms nearly show their duality.

Chancroid is a soft sore, or ulcer, coming on within forty-eight hours after exposure, capable of being produced on the patient or others by inoculation, accompanied by suppurating buboes, and followed by no constitutional symptoms.

Chancre, on the other hand, rarely manifests itself under twenty days after the impure intercourse. The sore is indurated and hard, non-suppurating buboes, not inoculable on patient or anyone having syphilis, followed by secondary constitutional symptoms, etc. These seem to prove that they are two separate and distinct diseases. I wish to report a case that seems almost positively to prove the unity of the diseases, or at least that secondary symptoms may follow chancroid.

A young man came to me some time ago, about three days after intercourse, with a well-developed case of chancroid. The sore was eaten into the parts, with excavated edges, but there was no hardness or induration. I inoculated his leg and a well-marked chancroid resulted. In a short time a bubo developed and went on to suppuration. Every indication pointed to chancroid, and chancroid only, and so I told my patient. The sore healed kindly under the use of dry calomel. What was my surprise to find, in about seven weeks, a case of secondary syphilis. The syphilides were present. Sore throat, etc. The young man positively asserted, and I believe truthfully, that he never had but this one intercourse in his life. The mercurial treatment soon controlled the symptoms.

At his special request I visited the girl with whom he had had the intercourse. I examined her thoroughly. She evidently, at the time of intercourse, had a chancroid, but at this time it was entirely healed. There was not the slightest indication of any secondary symptoms, which proved to my mind that she had no syphilis. She had taken no medicine for syphilis, so the symptoms could not have been masked. She stated that she had had no intercourse with anyone for several days prior to this time. This young man had the connection with her on a Sunday night. On the Thursday night before she had intercourse with a drummer, a stranger to her. Is it possible that this drummer could have deposited syphilitic virus in her vagina at that time, which remained inert until the Sunday night when the young man had intercourse with her? If so, why was the girl not affected, as she no doubt had a chancroidal sore at the time? I have watched her closely, and no syphilitic symptoms have shown themselves, and it is now over three months since the occurrence. I called it a missed case. Still, if my patient had chancre, why was it not indurated? Why was it inoculable? Why did the initial sore develop so soon? If it was simply chancroid, why the secondary symptoms? Why was it controlled by specific treatment?

I do not fully understand the case. This I do believe, however, he had chancroid, and he also had constitutional syphilis.

ENORMOUS HYDATID CYST OF RIGHT KIDNEY—AUTOPSY.

By A. L. STAVELY, M.D.,

READING, PA.

The kidney is so seldom chosen as the seat of this very rare growth that, unless the urine betrays the secret of its existence, or rupture occur, it is very apt to be overlooked. Owing to the obscurity generally connected with such cases, it is well to call the attention of the medical public to them when they occur. The case in question, George Starok, a Russian Pole, forty-three years of age, was admitted to the Reading Hospital on March 3, 1889, with a temperature of 101½° F.; pulse, 88; respiration, 24; suffering intense lancinating pain anteriorly, just below the thorax, and extending around to the back. The past history was very meagre, owing to inability to understand him. About two months before admission, he first became conscious of something wrong from severe pain that he experienced whenever he would attempt to work. The patient was quite well preserved, though his eyes were sunken and face indicative of suffering.

Inspection revealed a very marked prominence of the lower part of the thorax and the upper part of the abdomen, with labored inspirations, and pulsation below the ensiform cartilage. On palpation a large, firm mass could be felt, extending about four inches below the margin of the ribs. One of the hospital physicians thought that he could detect fluctuation, but the demonstration of it was so uncertain that no importance was attached to it.

Percussion gave the following results: Over the sternal region the line of dulness was seven inches, the lower limit being from two to three inches above the ensiform cartilage. The length in the right nipple line was ten inches, dulness beginning at the nipple. In the right mid-axillary region dulness extended seven inches, beginning at the eighth intercostal space. Posteriorly, on the right side, decided dulness began at tenth rib, the lower boundary being obscure. Dulness extended over to the left mid-axillary line, where it began at the seventh intercostal space and extended to the edge of the thorax. Auscultation demonstrated encroachment of the mass upon the right lung. The pain continued after admission, and had to be relieved by hypodermics of morphine and atropine. The stools, which, with one or two exceptions, were loose, varied from light to dark green in color, and were about normal as to frequency. His urine was slightly darker than normal, and contained no albumin nor anything else that could be of assistance in making a diagnosis. There was no jaundice nor anything but the stools which would indicate any hepatic disturbance. He was placed upon liquid diet, and owing to the uncertain diagnosis no especial medical treatment was adopted. The pulse varied from 72 to 100, the respirations from 19 to 30, the temperature averaging about 99° F. On April 11th he complained of excruciating pain, and frequent resort was made to the hypodermic syringe. On the morning of the 12th he went to the bath-room for a wash, and was there only a minute, when he came rushing out and, dropping on the floor by his bed, expired.

At the autopsy the following condition was found:

On opening the abdomen a large, tense, fibrous sac was seen, and, by manipulation, was found to have liquid contents. The liver was pushed upward and to the left, so far that the gall-bladder occupied a position on the left side corresponding to its normal position on the right. Outside of flattening, the organ was not otherwise affected. The heart was forced a little to the left. The vena cava was pushed anteriorly by the cyst, and was two to three inches away from its normal position.

The ascending and transverse colon was fastened by close, fibrous attachments to the wall of the cyst, so firmly that it was difficult to separate them. The diaphragm was so intimately united that it could not be dissected from the cyst, but had, in part, to be removed with it. On feeling for the right kidney, it was discovered that its position was occupied by this enormous body, and the kidney was not to be found. In trying to remove the cyst, the manipulator's finger forced its way through a weak spot, and over nine pints of a clear, odorless, serous-like fluid escaped, and floating in the fluid, was found a solitary daughter-cyst, about half an inch in diameter. After great difficulty the cyst was removed, and was found to contain a thick, white, membranous mass floating in some liquid. The membrane, or more properly, the cyst-wall, was distinctly laminated, and looked something like boiled albumin. One surface was slightly roughened, and had on it, here and there, aggregated nodular masses, which proved to be echinococci buds. The other surface of the cyst-wall was smoother and had on it thin layers of a jelly-like consistence, which were easily attached, and which seemed to be a more recent formation. Examination of the sac that contained the hydatid cyst, demonstrated the fact that it was nothing but a dilated kidney, the ureter of which had become entirely occluded, and the lateral halves of which were imbedded in the walls of the sac at about two inches distance from each other, and feeling like masses of muscular tissue. The walls were composed of bands of fibrous tissue running irregularly in every direction, being thinner in one place than another. The inside of the sac, or what presumably corresponds to the pelvis of the kidney, was smooth. Microscopic examination of the cystic fluid revealed a number of echinococci hooklets, and crystals of chloride of sodium were discovered on evaporation. The fluid was somewhat acid and gave a slight albuminous reaction. The left kidney was much enlarged, weighing 12⅜ ounces. There was no degeneration as yet, and the hypertrophy was due entirely to vicarious action. The spleen weighed 12½ ounces, was very brittle in consistence and deeply congested. The heart was somewhat dilated, and there was some fibrinous deposit about the mitral and aortic semilunar valves. No apparent lesion of any other organ was recognizable.

THERAPEUTIC VALUE OF PHENACETINE.

By THOMAS W. AYERS, M.D.,

JACKSONVILLE, ALA.

For the past few years I have been using antipyrin for its value as an antipyretic and an antineuralgic, but as in several instances in my practice untoward results have been produced, where cyanosis, vomiting, disturbed respiration and circulation have followed doses which, to other patients and in other circumstances, had been administered with impunity, and on account of the monopoly, and unreasonable price charged for it by the manufacturer, I was delighted when I saw the announcement that phenacetine, a new remedial agent which was superior to antipyrin in its therapeutic value as an antithermic and antineuralgic, without toxic phenomena, and which was being sold for a less price, had been placed before the profession.

After seeing the first few notices of phenacetine through the journals, I had my druggist make an order for it, and since then have prescribed it freely, and, as compared with antipyrin, I have been delighted with the results which I have obtained from its use.

As an antipyretic I have had nothing but the very best results from its use. The time at which the temperature commences to fall when phenacetine has been given in pyrexia is usually not more than thirty minutes, and the maximum lowering occurs in about three hours. The duration of the reduction is usually from four to six hours; but, of course, much depends upon the dose given and the disease being treated. Ten grains will be found to be usually sufficient to lower the high temperature by three degrees, after the lapse of from two to four hours. The transition of the high temperature to the lower, and *vice versa*, is a gradual one. After large doses, say fifteen to twenty grains, have been administered, profuse perspiration occurs, but no bad consequences supervene. Have

not had it produce a cutaneous rash like that produced by antipyrin and other antipyretics.

As an antineuralgic, there is no question but it is superior to antipyrin. It is much more energetic in its action than either antipyrin or antifibrin. The effect of the drug is manifest, as a rule, in thirty minutes after the administration of the first dose. If relief is not obtained in from thirty to sixty minutes, a second dose is given; but I have rarely had to give the second dose to relieve any painful affection. The results obtained in the treatment of neuralgias and migraine indicate that all paroxysmal pain is especially susceptible to treatment by this remedy. I have prescribed it, among other affections, for occipital neuralgia, hemicrania or vaso-motor cephalalgia, facial neuralgia, and dorso-intercostal neuralgia, and in no case has it failed to give marked relief, and the pain usually disappears in thirty to sixty minutes. I have noticed in several instances that its sedative action is accompanied by a decided hypnotic effect. I had a patient this week who suffered intense pain from dental neuralgia. I prescribed for her twenty grains of phenacetine. In forty minutes she was entirely relieved of pain, and slept soundly. The pain returned with great intensity in eight hours after the dose of phenacetine had been administered. Again gave her twenty grains of phenacetine. In thirty minutes she was perfectly easy, and soon slept soundly. In six or eight hours she had a return of the pain, which yielded as before to the effects of phenacetine. I also had a patient this week who suffered from excruciating, darting, lancinating pains along the distribution of the ophthalmic division of the trigeminus. He had taken antipyrin and morphine, with negative results. I prescribed for him twenty grains of phenacetine. In thirty minutes the effect of the drug was manifest. In one hour he was entirely easy, and the pain did not again return. I could cite other cases with results similar to the two given, but as I wish to make this article brief, I will desist, and simply state that in no instance have I been disappointed in this drug as an antineuralgic.

Dosage.—As an antipyretic, I think it should be given in eight to ten grain doses, to be repeated as often as is necessary to control the temperature. My observations show ten grains, to adults, repeated every six hours, to be a sufficient dose in febrile cases. For the relief of pain in neuralgia, etc., I find it necessary to give from fifteen to twenty grains to obtain relief from one dose. I have given as much as sixty grains in nine hours, and have had no evil results from its use.

SINGULAR CASE OF MULTIPLE LABOR AND ITS MANAGEMENT.

By R. RANDOLPH BALL, M.D.,

ASSISTANT SURGEON, U. S. ARMY.

Shortly after returning from a leave of absence, in January, 1889, I was requested by my friend Dr. G—— to see a singular case of labor he was then attending. The patient was a robust laboring woman, thirty-eight years of age, and had given birth to a healthy child on February 6, 1888, although the labor, I was told, had been a difficult one, requiring delivery by forceps. Dr. G—— had been called to attend this woman on the night of February 1, 1889, and, finding her in labor, had remained and delivered her of a full-term male child. On his arrival he found her walking about the room (between the pains). She was directed to go to bed, but before reaching it a heavy pain seized her, expelling the child while she was in the upright position. She was then placed in bed, the cord tied and cut, and the woman was made as comfortable as possible. After the expulsion of this child the womb quieted down, and there was not the slightest return of pain to indicate a desire to expel the placenta. At this time gentle traction was made on the cord, with no effect, and it was then noted that the abdomen was unusually large, and, on carrying the finger up the cord, some slight resistance was noted on deep pressure into the cavity of the womb. Seeing this condition of affairs, Dr. G—— suspected the existence of a second child; and, it being impossible to know positively whether there existed one placenta or two (which, of course, was a paramount question), he decided to postpone further action, simply ordering her a carbolized douche, and to be kept quietly in bed.

On February 2d, the next morning, he desired me to see the case with him. On passing the finger up the cord a peculiar resistance was felt, which seemed to me like the surface of a knee; the placenta was firmly attached; the abdomen, although large and resisting, was so covered with fat that I found it impossible to make out anything by palpation. No definite heart-sounds were discoverable through the stethoscope. Although the most definite diagnostic point I was able to discover was the sensation produced on the end of the finger when passed up the cord, I stated my belief that another child existed in the womb, and that a system of "waiting and watching" alone was indicated for the woman's welfare; to this Dr. G—— readily agreed, as he thought likewise. The reasons for this conclusion were: 1, The almost certain existence of a second child; 2, the possible existence of only one placenta and, in this event, the fatal result to the child by its forcible extraction at this stage of the case; and, 3, the comparative safety of the mother at present, there being no hemorrhage whatever, with complete cessation of all uterine pains.

We then ordered warm carbolized douches twice daily, and that she remain quietly in bed, reassuring her that there was no cause for interference or uneasiness, and left her comfortable. Dr. G——, having imperative duties on hand, requested me to look after the case till further developments.

I saw the patient twice daily, until the evening of February 9th. On my visit then I found that the pains had become more frequent and more intense; the woman was restless, and complaining a good deal. On examination the os was found to be quite patulous and soft; the head was well down, presenting in the first position. We now hoped the case would soon terminate by natural means; but it was soon evident that this was not to be, complete uterine inertia coming on soon afterward. A few minims of ergot were then given, with no decided effect. This was given most sparingly, lest it might retard all future efforts in the case, and thus prove deleterious to both mother and child. I then advised the forceps, applied them, and easily delivered a healthy male child of full term and slightly over. After the delivery of the child the womb continued to show no sign whatever of activity. It was evident now that the only safety for the mother depended upon the thorough extraction of the placenta or placentæ; there being no longer any doubt that we had an additional trouble (retained placentæ) to deal with. Brandy was now given, the patient being much exhausted, when I carried one hand up into the womb and succeeded in gradually enucleating the first placenta, which was firmly adherent and located on the right-hand side of the cavity of the womb, nearly opposite the left Fallopian tube. Of course, before carrying the hand into the cavity, thorough cleanliness was observed, and carbolized oil, two per cent., was applied. After the delivery of this placenta it was examined, and found almost complete, but with only one cord attachment.

The patient was then allowed to rest half an hour, when I again carried my hand into the womb and delivered the second placenta, which was also firmly attached, on the left-hand side of the cavity, just below the Fallopian tube. On detaching this placenta a profuse gush of blood occurred, greatly prostrating the patient, but with stimulants and lowering of head she revived; at the same time constant kneading of the womb was continued, which greatly aided in checking the hemorrhage. In two hours, the patient having thoroughly reacted, she was placed in bed and a hot carbolized douche ordered. On the evening of the 10th, at my visit, I found the tempera-

ture 100° F.; pulse, 98. Carbolized douches were ordered every four hours, with quinine in twenty-grain doses.

On the following evening the temperature was 103° F.; pulse, 120; patient restless and complaining of pain over the womb, the lochia being scant and very foul; urine had passed normally. At this point Dr. G—— and I both agreed that intra-uterine douches were indicated. A long recurrent male catheter (metal) was then disinfected in a one to one thousand bichloride solution and attached to a fountain-syringe, which I carried up into the womb, and the whole cavity was thoroughly douched out with hot carbolized two per cent. solution.

On my visit on the morning of the 12th the temperature had fallen to 102° F., and the patient was fairly comfortable. The douche was again used, and twice on each successive day, morning and evening, for one week following. It was noticed on the third day after its adoption that the temperature had become normal, and the general condition of the patient was better. She then continued to improve, and in four weeks was able to be about her house.

The points of interest in this case are the exceeding fertility of this mother, bearing three children in a little less than twelve months, the length of delay between the first and second child, the existence of two placentæ and the adherence of both, and the marked benefit noted after the use of the intra-uterine douche. In using this latter I found it was not possible to make the water return by the recurrent tube, but by depressing the womb backward it returned freely by the side of the instrument. Of course, great caution must be taken to see that the water does return freely. I am aware of the dangers imputed to intra-uterine injections, but, if carefully managed in well-selected cases, I believe the benefit undoubted. As a further point in connection with this case I may mention that the husband is a man sixty years of age, who had already been the head of two families, and had recently wedded his able coadjutor with the sole idea, he said, of "taking a little comfort in his old age."

PAROTITIS COMMUNICATED FROM BOY TO DOG.

By A. G. P. POORE, M.D.,
WALLONIA, KY.

Case I.—J. D——, a boy, aged seventeen; well-grown for a boy of his age; previous history only fair. Was exposed to mumps on Christmas Eve, at a party given to the young people. Just fourteen days from that date he found that he also had mumps, as many at the gathering on Christmas Eve had. They stayed in his jaws and under his ears just five days, and then they began to jump; they went down to the testicles, and he suffered all the ills that he could in that locality and recovered, with atrophy, however, of those parts.

The patient is now quiet and unassuming, and never boisterous, willing to "live and let live," an attribute he did not possess previous to having the mumps.

Case II.—A dog, belonging to the above-mentioned J. D——. The dog was very fond of him, and stayed in the house under the bed that his master lay on. Previous history good, and he always stayed at home and never fought other dogs. Just fourteen days after his master was taken with the mumps it was noticed that the dog was flopping his ears, and was very much swollen thereabout, and it was thought that he was afflicted with the same malady. This was subsequently proven to be a fact, for just five days after his ears swelled the testicles became enlarged; they still remain much hypertrophied, and J. D—— wants another dog—one that looks well in society.

This dog is now boisterous, will not cultivate friendly relations with any dog of his sex, and does not stay with the boy, as he did prior to having the mumps, but seeks other company.

I would be glad to have an explanation of the occurrence in each case, both human and canine.

FATAL CASE OF DIPHTHERITIC PARALYSIS.

By J. B. STAIR, M.D.,
SPIRIT LAKE, IA.

On February 2, 1889, I was called to attend Lida V——, aged nine, whom I found suffering from diphtheria of twenty-four hours' duration. The disease ran a moderately severe course of five days, at which time the deposit had wholly disappeared, the mucous membrane looked healthy, and restoration to health seemed certain and speedy. Considerable feebleness followed, however, and strength was regained slowly. About four weeks subsequently the little girl laughingly called her mother's attention to the fact that in drinking water some of the liquid refused to "go the right way," but came back through the nose; this difficulty in swallowing was a persistent symptom and became quite troublesome later. Paralysis of the vocal muscles also appeared early, and speech was painfully incoherent. Soon following this the disease attacked the lower limbs, and for a week she could not walk without assistance; but this disappeared to a great extent later. The arms were at no time affected. With some variation as to location there was little change for three weeks. Three or four days before death considerable somnolence developed. But the fatal result was directly due to paralysis of the heart and respiratory muscles, symptoms of which were speedily followed by death.

I have attended twelve cases of diphtheria within the three months past, some of which were much more severe than this one, but in none other were paralytic symptoms manifested, save in one, which had a temporary squint.

HYPERMETROPIC ASTIGMATISM.

Dr. J. A. Tenney, of Boston, Mass., writes: "Dr. Mitchell's case of simple hypermetropic astigmatism, reported in your issue of March 16th, recalled to my mind a similar case I had two years ago, the main features of which I copy from my case-book. Mrs. Alice C——, forty-nine years of age, engaged in teaching in a public school nearly nine months in the year, consulted me, to see if she could be made to see with spectacles. She said she did not believe she had ever been able to see like other people. She was wearing +5 D., O. U., for near work, but her spectacles gave her very imperfect vision. Her vision was $\frac{20}{100}$ in each eye. With a +5.5 D. cyl., axis 95°, her right eye could see $\frac{20}{15}$; and the same cylinder for the left, axis 100°, gave her the same vision in that eye. She could partly see a line lower on the test card. There was no lid trouble. The lady had three dioptres of presbyopia, which fact proved to my mind that neglected optical defects hasten that condition."

AN APPARATUS FOR MAINTAINING THE LITHOTOMY POSITION.

Dr. Horace Packard, of Boston, writes: "I desire to call the attention of the readers of The Medical Record to an exceedingly convenient device for maintaining the lithotomy position. It consists of the McBride yoke with a new pattern of shoulder-straps, giving much greater stability and causing the whole strain to fall upon the shoulders instead of about the neck as in the original form of this arrangement. The shoulder-pieces are triangular, and cut so as to fit the slope of the shoulders, and are fastened together by a cross-strap, passing through a buckle. By the aid of other buckles attached to the straps passing to the crutch, the shoulder-straps may be altered so as to fit any person.

The State Medical Society of Wisconsin.—The next meeting of the State Medical Society of Wisconsin will be held in Milwaukee, commencing on the first Tuesday in June.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, May 18, 1889.

A NEW STUDY OF THE ETIOLOGY OF DIPHTHERIA.

IN the *American Journal of the Medical Sciences* for April and May, 1889, Dr. T. Mitchell Prudden contributes the results of a prolonged and painstaking bacteriological study of the etiology of diphtheria. Dr. Prudden gives an interesting account of the development of our present views of the pathology of this disease, and of the bacteriological investigations made by recent observers.

There are, perhaps, still some physicians who believe that pseudo-membranous laryngitis, or croup, is always a different disease from diphtheria. While it is probable that occasionally a croupous laryngitis exists, not due to agents which infect the system, or have contagious properties, such forms are not frequent. The positive differentiation of croup from diphtheria could only be made by finding a separate specific micro-organism, or other material agent, for each clinical type, a thing which has not been done and which seems unlikely ever to be accomplished.

The micro-organism which has heretofore most often been found associated with diphtheria is the bacillus of Loeffler and Klebs. This has been found and cultivated by Loeffler, Klebs, D'Espine, V. Hoffmann, and Roux and Yersin. These and other observers have also found a streptococcus and several other forms.

Dr. Prudden's observations were made upon material taken from twenty-four cases of diphtheria.

He did not find the bacillus of Loeffler in any case.

The only species of bacteria present in almost all cases (all but two), was a streptococcus which he calls a streptococcus diphtheriæ. Next in frequency were certain pyogenic staphylococci which are abundantly found in other diseased conditions.

The streptococcus diphtheriæ consists of sphero-bacteria or cocci averaging one micromillimeter in diameter, and tending to form chains as they grow. This micro-organism was cultivated and the cultures injected into eighty animals, rabbits, hens, and pigeons.

In no case was a typical diphtheria produced; but in many there was marked local or general disturbance, such as suppuration, erysipelas, local necrosis, or diphtheria. Dr. Prudden, however, doubts if true diphtheria can be induced in the lower animals experimented upon; and on the whole he thinks he is abundantly justified in believing that his "streptococcus diphtheriæ" is, in a certain class of cases at least, the cause of diphtheria.

In further support of this view he found that, out of forty cases in which scrapings from throats of children not having diphtheria were cultivated, the streptococcus diphtheriæ was found in twelve instances. These children, however, were all living in wards in which diphtheria had existed, and two of them subsequently developed diphtheria and died. On the other hand, among thirty-one children outside the hospital who were examined, the streptococcus was found in only two cases, and in both of these diphtheria subsequently developed.

Dr. Prudden cannot find any difference, morphologically or in their mode of growth, between the streptococcus found in diphtheria and the streptococcus pyogenes and streptococcus erysipelatos. Bacteriological studies point to an identity in some of their phases between the phlegmonous inflammation, erysipelas, and diphtheria.

A number of experiments were made with regard to the action of disinfectants upon the streptococcus. Regarding this, Dr. Prudden states in his summary: "We have demonstrated that the streptococcus of diphtheria is not readily destroyed by drying, but both in the form of pure cultures on threads and fabrics, and in the pseudo-membrane itself, may retain its vitality for long periods when dried in the air. We have tested its vulnerability when brought in contact with some of the commonly used antiseptic agents, and found first, that the vapor of burning sulphur is very inefficient and unreliable in destroying the germs. We have found that carbolic acid and creolin in considerable strength destroy the streptococci, but in dilute solutions are inefficient; while sublimate, even in very dilute solutions, heads the list in its killing power. But we have also found, as was to be expected, that all of these germicides are much less efficient when applied to the bacteria which lie embedded in the pseudo-membranes and the tissues, than when they are free in the pure cultures."

Our writer is particularly severe upon the time-honored process of sulphur fumigation. Of it he says:

"It is a great pity that in the matter of disinfection of rooms we should, in this region, still be going through with the inefficient mummery of burning sulphur with closed doors, under the impression that it will destroy contagion. This operation has, indeed, a certain archaic picturesqueness about it, and save for the damage that is liable to accrue from the fading of the furniture and hangings, is a tolerably harmless practice; but it savors rather of the propitiatory sacrifices to malevolent deities of centuries gone by than of the intelligence of the present time. Sulphurous acid, as it is usually applied in house disinfection, has been shown over and over again, by the most careful experiments, to be a very inefficient and unreliable disinfecting agent. It may be better than nothing, but in disinfectants—which are often our sole weapons in fighting epidemics—the best is none too good. The efficiency of sulphurous acid may be increased by securing the thorough wetting of everything to be disinfected, but even then it is not great."

The measures suggested in place of the sulphur are removal and burning, or boiling, after soaking in two per cent. carbolic solution, all clothing, bed-linen, hangings, etc. Then everything must be washed in two or five per cent. carbolic acid solutions.

"The obvious lesson taught by a definite conception of the nature of the germ which causes diphtheria is not to dally with fancy mixtures which have at best a moderate germicidal power, but to get at the growing germ, as directly as the seat of the lesion will permit, with some agent which we know will kill it.

"It does not lie within the scope of this paper to suggest any detail as to the treatment of diphtheria. But the points which I would especially emphasize are: First, the evidence here adduced that the germ primarily gains a foothold at the seat of the local lesions, inducing its general effects upon the body at large by the local production of an absorbed ptomaïne; second, the vulnerability of the germ to certain commonly employed germicides; third, the propriety of making germicidal applications to the mouths and throats of individuals liable to infection. It will thus be seen that the immediate practical outcome of these studies, so far as the treatment is concerned, is rather to confirm the importance of local antiseptic methods, and to give precision to the ends which we may hope to attain by them, than the suggestion of anything new."

A POINT IN SCRIPTURE HISTORY.

SEVERAL correspondents of the *British Medical Journal* have been discussing the subject of the physical causes of the death of Christ. M. Ernest Renan, in his "Life of Jesus," says: "Everything tends to show that the instantaneous rupture of a vessel in the heart killed Him at the end of three hours." It may be assumed that M. Renan thought that Christ died from the rupture of an aneurism; if so, the French critic who, in his autobiography, speaks so complacently of his mastery of all human knowledge, is not fortunate in his pathological descriptions.

Sir James Simpson ventured the opinion that Christ's death was caused by a "broken" or ruptured heart. A correspondent of the *British Medical Journal*, Dr. Molony, thinks that there was a pleuritic effusion; while Dr. Charles Steele writes: "I have always felt that the actual morbid condition was either distention of the heart with blood, and coagulation with separation of serum, or effusion of serum into the pericardium. For, while exposure, abstinence, and extreme fatigue existed, in addition there existed mental agony, described in its early period as inducing 'sweat-like great drops of blood falling down to the ground,' of which we can form no conception; and then the check to cerebral circulation produced by the prolonged elevation of the arms of our blessed Lord; then the extreme mental anguish expressed in the words, 'Eloi, Eloi, lama sabachthani;' then the intense relief of the power to say, 'Father, into Thy hands I commit my spirit.' The Roman soldier, we may be sure, struck at the heart, and well knew where it was situated. This we can see in the well-known statues of 'The Gladiators,' where the vanquished one is exposing his distended left thorax to the stiffened flattened hand of his antagonist, who is destined to tear his heart out. The pleuritic effusion theory would induce the idea that if crucifixion had been avoided death might have resulted from natural causes, and would not account for the separate mention of blood and water."

It appears to us that all these speculations are futile and barren; and we have no doubt that very many of our readers will agree with a correspondent, who writes regarding the "points" made by those who have discussed this subject: "No doubt such points may meet the approval of some men, and, judging them from a purely scientific view, no doubt have their points; but I cannot but think that such a serious, awful, and mysterious subject as the death of our blessed Lord should have no question of science (pure and simple) applied to it; in fact, that it is nothing short of sacrilege to treat such a subject on scientific grounds. Your correspondent speaks of our Lord's death as if it were not miraculous; of course, it was both miraculous and a mystery; and so, in my opinion, and in that of a good many others, it should be allowed to rest as too deep, serious, and awful a subject to discuss in a scientific point of view."

THE PREVENTION OF PHTHISIS.

WHILE the infectiousness and contagiousness of phthisis are generally admitted, there has as yet been little attempted in the way of prevention of the disease by means adapted to kill the specific micro-organism. A systematic study of this branch of prophylaxis has recently been made by Dr. Cornet, who read a paper on the subject before the Berlin Medical Society, on March 13th (*Brit. Med. Journal*).

The chief danger, Dr. Cornet thinks, lies in the dried sputum, which becomes turned into a respirable dust. The habit of spitting on the floor is, he thinks, therefore an extremely bad one. In the expression of this opinion Dr. Cornet may be giving utterance to a great prophylactic truth, but he at the same time aims a subtle blow at one of the most cherished habits of the American legislator, who, however, we may add in justice, generally disinfects his sputum with the juice of the tobacco plant. Dr. Cornet, however, insists that in all closed rooms the expectoration must be voided into a spittoon. This plan is simple, does not interfere with social conditions, and entails no heavy expense.

"Cave sputum" is the motto of phthisical prophylaxis. All sputum should be disinfected, or its possible virulence destroyed in some way. Little confidence should be placed in disinfection alone. A five per cent. solution of carbolic acid kills tubercle bacilli only after twenty-four hours; a 1 in 1,000 sublimate solution still later. Sputum should not on any account be left so long.

Dr. Cornet gives a long list of special recommendations. Phthisical patients, he says, should wear their beards short, should use their own spoons, glasses, etc., should avoid kissing on the mouth, etc. If death occurs, the walls of the room inhabited by the deceased should be rubbed with freshly baked bread. Furniture, beds, and linen must be disinfected. Prophylaxis, however, should not begin when the disease breaks out in a family, but the entrance of tuberculosis into the family should be prevented. Neither a consumptive mother nor a consumptive wet-nurse should suckle a child. Cow's milk should be used only when well boiled. Children must early be made to give up the bad habit of putting all possible objects into their mouths. All contact with strangers must be closely watched. Healthy servants should be chosen. Diseased children should be kept away from school. The cleaning of apartments should be carried out as far as possible

without raising dust. In changing houses the walls should be cleaned. Spittoons should be placed in all rooms, on staircases, in offices, factories, etc. Public disinfecting establishments must be constructed. In hospitals isolation of phthisical patients is desirable. An inquiry has shown that the hasty dipping of a laryngoscope into a five per cent. carbolic-acid solution is not sufficient to obviate the danger of infection; it is, therefore, necessary to use a special mirror for each patient. The use of tuberculous meat, and of milk from tuberculous cows, must be prevented by legislative enactment. Special institutions for phthisical patients should be established outside cities.

All this is calculated to add considerably to the burden of having phthisis or having its care. We suspect that it will be a good while before the antiseptic prophylaxis of phthisis is widely adopted; and we doubt very much the wisdom of inoculating society with too deep a sense of the contagiousness of consumption.

News of the Week.

DR. CLEMENT CLEVELAND has been appointed surgeon to the Woman's Hospital in this city.

DR. FREDERICK J. BROCKWAY, of this city, has been appointed House Surgeon to Johns Hopkins Hospital, Baltimore.

"THE MEMPHIS JOURNAL OF THE MEDICAL SCIENCES" is the name of a new medical monthly edited by several physicians of Memphis, Tenn.

FOR KENTUCKY LADIES ONLY.—The Kentucky Senate has passed a bill providing for the appointment of women physicians as assistants in the insane asylums. Residents of other States who have been born in Kentucky will be eligible.

A SENSATIONAL STORY is published in the daily papers to the effect that a young physician accidentally strangled himself while experimenting with Sayre's suspension apparatus.

THE HOSPITAL OF THE WOMEN'S TEMPERANCE HOSPITAL ASSOCIATION OF CHICAGO, which was organized by friends of regular medicine, has, it is said, been captured by certain lady homœopaths.—*Times and Register.*

POLITICS AND HOSPITAL APPOINTMENTS.—We learn from the *Medical and Surgical Reporter* that the Mayor of Philadelphia instructed the President of the Board of Charities and Correction to order the Medical Board to nominate a certain candidate. This the Medical Board refused to do, whereupon the Mayor issued an order that the President of the Board be dismissed, and appointed a new member of the Board and a new president. This action of the Mayor is said to have been instigated by "the representatives of a medical school which has failed to secure the respect of the most intelligent and conscientious members of the medical profession in Philadelphia, and which has been so conducted that this last step is no surprise to those who have watched it carefully."

THE COLLEGE OF MEDICINE of the University of Southern California graduated a class of two at its Commencement, April 12th.

"THE MEDICAL EXAMINER."—A new monthly journal under this name has appeared, devoted to the interests of the medical practitioner in his relations as a medical examiner for the army, navy, life insurance, civil service, etc.

THE GERMAN SURGICAL CONGRESS was held at Berlin, beginning April 24th, and was opened by the president, Professor von Bergmann. Mr. Victor Horsley, of London, was present, and made some notable demonstrations on the subject of cerebral localizations. Much interest was excited also by the address of a Japanese physician, Dr. Kitassata, who, under the direction of Privy Councillor Robert Koch, has succeeded in obtaining pure cultures of the bacilli of tetanus. The Congress held seven sittings. The presidentship for next year was, on the afternoon of the third day, again conferred on Professor von Bergmann. The close of the Congress took place on the afternoon of April 27th.
